### NOTES ON THE TREATMENT OF YELLOW FEVER WITH THE BLOOD-SERUM OF THE BACILLUS ICTEROIDES, AND ITS PREPARATION.

BY CHARLES B. FITZPATRICK, M.D.,

PATHOLOGIST AND DIRECTOR OF THE BACTERIOLOGICAL LABORATORIES OF THE NEW YORK HEALTH OFFICER'S DEPARTMENT, ASSISTANT BACTERIOLOGIST TO THE DEPARTMENT OF HEALTH, CITY OF NEW YORK, ETC.

THE manifest advantages of the serum treatment of yellow fever in both the prevention and cure of the disease caused Dr. Alvah H. Doty, health officer of the port of New York, to have undertaken a series of experiments in the laboratories of his department, under my direction, with the view of obtaining a serum for the treatment of yellow fever. I have now succeeded, after eighteen months of experimental work, in obtaining a serum which is both curative and preventive.

The work preliminary to the preparation of the serum was to obtain cultures of the micro-organism bearing an etiological relation to the disease. In March, 1897, I isolated a micro-organism from the blood of three cases of yellow fever in the Swinburne Island Hospital. This organism,[1] which I have designated as the bacillus coli icteroides, I regarded as a special, virulent form of the bacterium coli commune. This culture was obtained prior to the publication in the *Annales de l'Institut Pasteur*, of June, 1897, by Dr. José Sanarelli, of his article describing the bacillus icteroides, which he had found in some cases of yellow fever. Dr. Sanarelli was so kind as to send a culture of his bacillus to the New York health officer's department. Comparisons of this culture with that of the bacillus coli icteroides led me to conclude that these organisms were practically the same, and the pathogenic powers of these bacilli convinced me that they bore an etiological relation to yellow fever, notwithstanding their intimate connections with the bacterium coli commune. This conclusion was reached by giving more importance to their pathogenic virulence and their serum-therapeutic properties as proofs of a specific causative relation than to mere biological differences, such as peculiarities of colony formation, or different degrees of gas production, motility, and acidity. By serum-therapeutic properties I mean the power that specific pathogenic bacteria possess of producing toxins and causing to be formed in the blood of susceptible animals a substance which bears a preventive and curative relation to the specific disease.

The methods employed in the immunization of the animals to the bacillus icteroides are essentially the same as those pursued by me when I succeeded in obtaining the first diphtheria antitoxin serum used by the New York City health department for the free treatment of diphtheria in the public hospitals, and which I have already described at length in an article in the *New York Medical Journal*.[2] The culture used to produce the toxins and to inoculate the animals was the culture of the bacillus icteroides which Dr. Sanarelli sent to the health officer's department. Two horses were chosen to be subjected to the process of immunization, in order to obtain the preventive and curative serum from their blood. The injection fluid was made up of the living culture, or filtered cultures. The cultures were allowed to grow at 37° C. for about twenty-five days and then filtered. The filtrate contained a toxin of varying strength. The intra-jugular injection of two or three hundred cubic centimetres of the toxin was usually required to cause a reaction of two degrees in a horse which had undergone the process of immunization for fifteen months. The subcutaneous injections of the living culture are not well tolerated. They cause extensive necrosis of the subcutaneous tissues. The subcutaneous injections of the toxins are tolerated better than the cultures, but are not so satisfactory as the intravenous injections of the filtered toxin. The necrosis of the subcutaneous tissues resulting from extravasations of intravenous and subcutaneous injections was so extensive that it resulted in the death of one of the horses.

The virulence of the culture used has varied. The original culture sent to the laboratory by Dr. Sanarelli caused the death of a guinea-pig weighing 300 gm. in about seven days when injected in a dose of ½ c.c. or more intraperitoneally. I have increased the virulence of the culture so that the subcutaneous injection of ½ c.c. to 1 c.c. causes death. The culture now used acts as follows:

Guinea-pig, weight 235 gm. inoculated subcutaneously with 1 c.c. died in 6 days.
Guinea-pig, weight 235 gm. inoculated subcutaneously with 2 c.c. died in 3½ days.
Guinea-pig, weight 260 gm. inoculated subcutaneously with 3 c.c. died in 2½ days.

It is readily seen from the above that the culture does not cause in guinea-pigs a disease with a definite cycle, or an infection which has a definite period of incubation and development. The intensity of the infection depends upon the dose, and with a smaller dose death in some cases takes place as late as nineteen days after the infection. The character of the reaction in horses has been a direct rise of temperature within twenty-four hours and a fall to about normal within the next twenty-four hours. This is the typical reaction following intravenous injections. Subcutaneous injection and extravasation from the veins cause a more gradual descent, or a fall followed by a rise. The horse usually lies down after an injection and often develops long periods of weakness with loss of appetite. The horse which has lived was first injected on January 19, 1898, and has been methodically injected at the proper intervals to date.

Table showing injections and reactions of the horse.

January 19, 1898.—Subcutaneous injection of 1 c.c. of a 21-day living culture caused a temperature of 102° F.
February 23, 1898.—Subcutaneous injection of 3 c.c. of a living culture 33 days old caused a temperature of 102° F.
May 8, 1898.—Subcutaneous injection of 2 c.c. of a living culture caused a temperature of 102° F.
May 29, 1898.—Subcutaneous injection of 10 c.c. of a living culture 6 days old, containing 0.5 per cent carbolic acid caused a temperature of 102.3° F. with considerable prostration and swelling.

[1] Fitzpatrick: MEDICAL RECORD, January 29, 1898.
[2] Fitzpatrick: New York Medical Journal, April 27, 1895.

June 23 1898.—Subcutaneous injection of 9 c.c of a living culture 13 days old, containing 0.5 per cent carbolic acid, caused a temperature of 101 3° F

July 14 1898.—Subcutaneous injection of 12 c c. of a living culture 5 days old caused no rise of temperature.

July 18 1898.—Subcutaneous injection of 18 c.c of a 24-hour culture caused a temperature of 104 4° F.

July 30, 1898 —Subcutaneous injection of 50 c c. of a 24-hour culture caused a temperature of 102.1° F.

August 6 1898.—Subcutaneous injection of 105 c.c of a 24-hour culture caused a temperature of 103 2° F

August 21, 1898 —Subcutaneous injection of 150 c c of a 24-hour culture caused a temperature of 104 1° F

September 17, 18, and 19 1898 —Subcutaneous injections amounting to 116 c.c. of living cultures caused a temperature of 101 2° F.

October 18, 1898 —Subcutaneous injection of 35 c.c. of a living culture caused a temperature of 102° F.

November 22 1898.—Subcutaneous injection of 90 c c of a 7-day culture caused a temperature of 101 2° F

December 14 1898 —Subcutaneous injection of 112 c c. of a living culture caused a temperature of 101.4° F.

January 7 and 17 —Subcutaneous injection of 100 c.c of a living culture caused a temperature of 101.2° F

January 31 1899.—Subcutaneous injection of 100 c.c. of a living culture caused a temperature of 100 2° F.

February 18 1899.—800 c c of a living culture in drinking-water caused a temperature of 101 2° F

February 23, 1899.—325 c c of a living culture in drinking-water caused a temperature of 100 2° F

February 24, 1899.—325 c c. of a living culture in drinking-water caused a temperature of 100 2° F

February 24 1899.—600 c c of a living culture in drinking-water caused a temperature of 100 2° F

February 25, 1899 —600 c c. of a living culture in drinking-water caused a temperature of 100.2° F

February 28 1899.—800 c c of a living culture in drinking-water caused a temperature of 100 2° F

March 8 1899 —Subcutaneous injection of 300 c c. of a living culture caused a temperature of 103 2° F

March 11 1899 —Injection of 75 c c (intrajugular injection) caused a temperature of 103° F

March 18 1899 —97 c.c intrajugular injection caused a temperature of 102° F.

April 13 1899 —50 c.c. of filter culture (toxin) in jugular caused a temperature of 101° F.

April 17, 1899.—135 c c. of filter culture (toxin) in jugular caused a temperature of 101 3° F

April 22 1899.—170 c.c. of filter culture (toxin) in jugular caused a temperature of 100.2° F

May 2 1899 —300 c c of filter culture (toxin) in jugular caused a temperature of 100 2° F

May 10, 1899 —350 c c of filter culture (toxin) in jugular caused a temperature of 100 2° F.

May 13, 1899.—215 c.c of filter culture (toxin) in jugular caused a temperature of 100 4° F

May 10, 1899 —300 c c. of filter culture (toxin) in jugular caused a temperature of 101 4° F

June 9 1899 —225 c.c. of filter culture (toxin) in jugular caused a temperature of 101 4° F

June 15, 1899.—300 c c. of filter culture (toxin) in jugular caused a temperature of 101.2° F.

The blood serum of this horse first began to show therapeutic properties on October 18, 1898. The serum of that date was effective to the extent that when three guinea-pigs were inoculated with a fatal dose of a twenty-four-hour bouillon culture of the bacillus icteroides, and two of these had twelve hours previously received an injection of the blood serum, the two which had received the serum treatment remained alive two and three days longer than the guinea-pigs which had not received the serum treatment.

Table showing the beginning of the therapeutic action of the serum:

Guinea-pig, weight 245 gm., received a subcutaneous injection of 2 c.c. of serum November 6 1898 and in 12 hours later was inoculated with a fatal dose of the culture Died November 14, 1898, 10 A.M

Guinea pig, weight 255 gm. received a subcutaneous injection of 1 c c of serum. November 6, 1898 and 12 hours later was inoculated with a fatal dose of the culture. Died November 15 1898 10 A M

Guinea-pig, weight 255 gm received no injection of the serum, but was inoculated on November 6, 1898, at 9 P M with the same dose as above. Died November 12 1898.

The succeeding experiments gave varying results. On May 2, 1899, however, a much stronger serum was obtained. Fourteen cubic centimetres of this serum, when injected into a guinea-pig which was at the same time infected with a fatal dose of the culture, cured the animal so injected, and it has lived and remained perfectly well and healthy. If it had not received the serum injection, it would surely have died. This is proven by the death of another larger guinea-pig, which was injected with a fatal dose of the culture at the same time and under exactly the same conditions as the one treated and cured by the serum. The one which died eighteen days after the inoculation, although a larger and stronger animal than the animal which was cured, was treated in every way the same as the cured one, with the single difference that the one which died did not receive any injection of serum. A smaller dose of the serum (10 c.c.) succeeded in preventing the infection in a guinea-pig which was injected with a fatal dose of the bacillus icteroides twenty-four hours after it had received the injection of the serum. The control guinea-pig, which was inoculated at the same time and which received no serum, died in nine days. Both the guinea-pig which was cured and the one in which the infection was prevented have remained alive and well to this day, *i.e.*, over a month since the death of the animals which received no treatment with the serum.

Tables showing the preventive and curative action:

I Guinea-pig weight 350 gm. received 14 c.c. serum at 4 P M May 3, 1899. One hour afterward it received 3 c c of culture. It has remained alive and well

Control—Guinea-pig, weight 390 gm , received no serum, but was inoculated with 3 c.c of the same culture as I. It died May 21, 1899.

II Guinea-pig weight 330 gm., received 10 c.c. of serum at 4 P M May 3, 1899 and 24 hours afterward was inoculated with 3 c.c. of the culture It has remained alive and well.

Control—Guinea-pig weight 330 gm., received no serum as above, but was inoculated with 3 c.c. of the culture same as II. It died May 12, 1899

Serum obtained May 31st has also shown about the same strength as the serum obtained on May 2d. Ten cubic centimetres of this serum were sufficient to prevent infection and death in a guinea-pig 300 gm. in weight, although a much heavier guinea-pig, 372 gm. in weight, inoculated at the same time, and which received no serum treatment, died on June 16th.

The serum I have succeeded in preparing has been compared by a series of experiments with serum obtained from the laboratory of Dr. Sanarelli in Montevideo, Uruguay, and has given more uniform results than the South American serum.

June 23 1899

## A FURTHER CONTRIBUTION TO EXCLUSION OF THE INTESTINE.

By FREDERICK KAMMERER, M D

PROFESSOR OF CLINICAL SURGERY, CORNELL UNIVERSITY MEDICAL COLLEGE; SURGEON TO GERMAN AND ST FRANCIS HOSPITALS

The various methods of partial and complete exclusion of parts of the intestine for fecal fistulæ or intestinal neoplasms have of late been frequently employed in cases in which an operation at the seat of the disease itself has been found impracticable. It is, of course, evident that such measures should be employed only when resection and suture of the divided ends are impossible, whatever the condition for which the operation is undertaken. Not long ago, many surgeons were of the opinion that such extreme measures were not justifiable in cases of fecal fistulæ, but I have become convinced from reports in recent surgical literature, and from my own experience, that the indication for this special form of operation is more often pres-

ent than we have hitherto been willing to assume. We all know that fecal fistulæ in the right iliac region, following suppurative appendicitis, do generally close without any further surgical interference, and then in a very short time. But it has been my experience, when they persist for many months, that spontaneous closure is the exception, and resection of a wedge or of the entire circumference of the intestine is often impossible or does not effect a cure. For such failures the dense adhesions of the intestines after inflammatory and suppurative processes must be held responsible, a condition to which I have called attention in my previous publication on this subject.[1] Such adhesions exist, notwithstanding the assertions of some surgeons to the contrary, even when the fistulæ have been present for some time and the inflammatory condition within the peritoneum about them has gradually subsided, as shown by the following case:

A. F——, aged twenty-six years, has on repeated occasions suffered from attacks of appendicitis during the past years. He first came under my care on November 11, 1896. He had been suffering from one of his attacks in the right iliac fossa for the past few weeks, and had felt generally ill and feverish. In the region above mentioned, a tumor, about the size of a fist, was clearly made out, immediately above Poupart's ligament. At the highest point of this mass, an area of inflammation and fluctuation was present. While making an incision at this point, a small extraperitoneal abscess cavity was opened, which extended for two inches in an upward direction. This cavity was packed with gauze. When the latter was removed a few days later, a considerable quantity of fetid pus for the first time escaped from the wound, and a sinus was discovered at the bottom of the wound, along which a probe passed for about eight inches into the lumbar region. Here the point of the probe could be plainly felt through the posterior abdominal wall. To establish better drainage, and to clear up, if possible, the nature of the trouble, I made a posterior lumbar incision on November 30th, which disclosed no abscess cavity in this region, but only a continuation of the sinus up to the diaphragm. I was now rather inclined to assume a tuberculous lesion, but on introducing my finger in an upward direction a large fecal concretion was found, lying near the diaphragm. No trace of the appendix was discovered. On January 20, 1899, the openings showing no tendency to close, an anterior abdominal incision was made for the removal of the appendix. The latter was found lying in dense adhesions, immediately against and behind the cæcum, and its removal proved very difficult, many intestinal adhesions having to be broken up. The wounds were packed and allowed to granulate. On January 27th a large amount of fecal matter appeared in the dressings for the first time, and thereafter until the middle of April a continuous discharge of fæces from all the three incisions was observed. Several attempts were made during this time to close the opening in the cæcum, which was large enough easily to admit my index finger, and was situated at a distance of about three inches from the external abdominal wall. They were, however, unsuccessful. During this time also, as soon as the opening of the various sinuses would show a tendency to close, the patient would suffer from retention of pus and fecal matter, become feverish, and lose ground considerably. Therefore, on April 26th, a median incision was made. On introducing my hand into the abdominal cavity, the right iliac and hypochondriac regions were found to contain a mass of adherent intestines. I now seized a coil of small intestine, about four feet in length, which, however, unfortunately disappeared in both directions in the adhesions, and could not on this account be utilized in the formation of an anastomosis, as it was impossible to determine the direction of the intestinal current in it. The duodenum was therefore brought into the wound, and followed down as far as possible to the adhesions, the small intestines being passed through my fingers. At a distance of four inches from this point, the small intestine was divided transversely, its distal end closed with a double row of sutures, and its proximal end implanted into the middle of the transverse colon with a Murphy button. The patient's recovery was uneventful. The intestinal current was evidently immediately diverted from its former course, scarcely any regurgitation occurring into the ascending colon. Only faint traces of fecal matter now and then appeared in the pus at the site of the fistulæ. The patient's temperature, which for some time prior to operation had run as high as 104° F., now became normal and remained so, and his general condition immediately began to improve. The patient was out of bed in a few weeks, but the fistulæ were still open, and, although secreting only a small quantity, showed no tendency to close. On May 17, 1898, a little more than a year after the last operation, the patient was in splendid condition, having gained between fifty and sixty pounds in weight. The fistulæ occasionally would close and then reopen, discharging a small amount of light yellowish fluid matter with a distinctly feculent odor. This would happen about every six weeks, and was preceded by some discomfort and pain in the iliac fossa. On July 2, 1898, the abdomen was reopened. The seat of the implantation was easily found, and the union of the intestines at this point was seen to be perfect. Not the slightest contraction had occurred, although a year and three months had elapsed since the Murphy button had been used. The transverse colon was now divided immediately before the old implantation, and both ends of the bowel were closed with sutures, thus entirely shutting off from the fecal circulation more than six feet of the small and large intestine. On April 23, 1899, the patient again presented himself for examination. He showed a further gain of six pounds in weight. He still suffered from attacks occurring about every two months, accompanied by a somewhat more profuse discharge from his fistulæ. After the implantation, about a year and three months ago, his bowels had for a short time been very loose, but now they moved, on an average, once or twice a day. He has not felt any additional pain or discomfort in the abdomen since the last operation.

In the above case, more than six feet of the small and large intestine were first unilaterally, and later on completely, excluded from the fecal circulation. In speaking of "complete exclusion," we mean the withdrawal from the intestinal circulation of a loop of intestine by cross-section of the gut at two points, but we do not infer the absolute closure of this excluded loop, so that no communication is present between the lumen of the latter and the external surface of the body. This latter condition I will designate as "complete exclusion with occlusion," or, for brevity's sake, as "complete occlusion." Several contributions to the subject of complete occlusion have lately appeared, from which it would appear that the majority of surgeons now consider this operation inadmissible. I have referred to the experimental work of Salzer, Reichel, and others, and to the cases of Baracz,[1] Obalinski,[2] and Parkhill,[3] in my previous paper on the subject of "intestinal exclusion." Of late, further clinical data have been furnished by Narath,[4] Eiselsberg,[5] and Baracz.[6] The latest publication (1899) is

by Baracz. This author, after a careful review of the literature of the subject, has found four cases of successful complete occlusion. They are his own and Obalinski's case, to which I have referred, and one case each by Friele[1] and Wiesinger.[2] To these must be added Parkhill's[3] case, the only case in which part of the small intestine has been completely occluded, and one of my own, which I will describe later on, making in all six cases.

The question of complete occlusion is a very interesting one, and one of some practical importance, as palliative operations for the relief of intestinal fistulæ and neoplasms are so frequently undertaken at present. I therefore feel justified in giving a short synopsis of these six cases:

Case I. (Baracz, 1893).—Youth, aged nineteen years; chronic invagination of the ileum into the cæcum, forming a tumor of the right ileo-cæcal region. An attempt was made to resect the same, on the supposition of malignancy, but this proved impossible, owing to adhesions. The ileum and ascending colon were divided transversely, and the four open ends of the small and large intestine invaginated and closed by sutures. A lateral anastomosis was then made between the proximal end of the ileum and the distal end of the ascending colon. The excluded portion was twelve inches in length. For the first three days after operation the patient had symptoms of peritoneal irritation (vomiting, meteorism), but later on made an uneventful recovery, and is to-day perfectly well.

Case II. (Obalinski, 1894).—Girl, aged twenty-four years; fecal fistula in the right iliac region, for which a resection of the cæcum was made in April, 1894, the ileum and ascending colon being cut through, when it was found impossible to approximate the ileum to the colon. A cross section was then made through the beginning of the transverse colon. The distal end of the transverse colon was united to the cut surface of the ileum by an end-to-end suture, and the open ends of the ascending and the transverse colon were tightly sealed by sutures, entirely shutting off this portion of the large intestine (practically the ascending colon). The resected portion was found to be the seat of tuberculous infection. Fourteen months later a second laparotomy was done, and the excluded portion of the intestine was found collapsed or at least not markedly distended. In December, 1895, a second tumor formed in the right half of the abdomen, which opened spontaneously in July, 1896. In April, 1897, the abdomen was again opened, about three years after complete occlusion had been done. The occluded portion was entirely removed, and found to be eight inches long and three and a half inches in circumference. It contained dark brown fluid of an offensive odor. Its walls were of abnormal thickness, and at its lowest point was found an opening leading to the external fistula, which had formed almost a year ago. Several smaller ulcers within the intestine were present at the lower end, and two polypoid excrescences on the posterior wall; microscopical examination revealed a tuberculous condition of the ulcers, otherwise the mucous membrane was normal.

Case III. (Friele, 1895).—Man, aged sixty-four years; tumor at the junction of the transverse and descending colon; laparotomy; removal impossible; therefore, right inguinal colostomy, two weeks later second laparotomy, division of transverse and descending colon at suitable distance from tumor; end-to-end anastomosis of proximal end of transverse and distal end of descending colon. The distal end of the transverse and the proximal end of the descending colon were closed with sutures. Three weeks later, resection of the ascending colon for cure of inguinal anus was done. Although the patient made a perfect recovery from this last operation, and was discharged from the hospital, he succumbed to acute intestinal obstruction about eleven weeks after occlusion had been done. The autopsy showed adhesions of the small intestines and kinking at one point. The occluded portion was contracted, about seventeen inches long, and contained about 50 gm. of feculent material. The mucous membrane was normal, except at the site of the tumor, where it was ulcerated.

Case IV. (Wiesinger, 1895).—In a woman, aged thirty-one years, an artificial anus was established near the hepatic flexure of the colon, for ulcerative conditions of the upper part of the descending colon. After local treatment had been instituted through the artificial anus for some time without benefit, complete exclusion was practised upon the transverse and descending colon and part of the sigmoid flexure, by dividing the latter, closing its proximal end, and uniting its distal end with the proximal end of the ascending colon, which had been severed at the site of the artificial anus. The proximal end of the excluded portion was implanted into the abdominal wall, to allow the escape of secretions. For some time after exclusion was done a considerable amount of pus and mucus passed from the opening, but this finally ceased, and seven weeks later the fistula was closed by operation. We may assume that no untoward symptoms followed complete occlusion in this case, as the author has made no further report.

Case V. (Parkhill, 1894).—Man, aged twenty years; fecal fistula after operation for appendicitis. For its relief a section of the ileum was made, about three-quarters of an inch from what appeared to be the valve. The distal end of the ileum was closed and the proximal end implanted into the hepatic flexure of the colon by the aid of Murphy's button. Recovery was uneventful. The button passed on the thirteenth day. One and one-half months later a fecal fistula still persisted, and, although contracted, still allowed some regurgitation. A second operation was done, which consisted in dissecting the large bowel loose from its attachments, and cutting it across somewhat above the junction of the cæcum with the ascending colon. The distal opening in the colon was sutured. The cæcum was then dissected down to the ileo-cæcal valve, when it was found, on passing the finger through the latter, that the ileum had not been cut at its junction with the cæcum at the first operation, as the end of the intestine could not be reached. The cæcum was now excised and the open end of the ileum closed, thus completely occluding a segment of the small intestine of unknown length. Before the last operation, the anastomosis between the ileum and colon, previously established, was examined by passing the index finger into the fistula, and it was found that the tip of the finger could barely enter the same, although the largest Murphy button had been used, and only forty-two days had intervened between the time of the passing of the button and the second operation. The patient was well one and a half months after operation. The author concludes that "while on first thought it seemed rather a rash procedure, its results show that it is not only justifiable, but also to be commended."

Case VI. (Kammerer,[1] 1896).—A man, aged forty-eight years, was operated on three times for appendicitis by a prominent surgeon; there was a large fecal fistula in the right iliac region. In February, 1896, an attempt was made to close the same by dissecting the large bowel and making a partial resection. The attempt failed. In March, 1896, the ileum was divided six inches before the ileo-cæcal valve, and its proximal

[1] For part of history, see Medical Record, February 20, 1897.

end implanted into the transverse colon (Murphy button), its distal end being closed by sutures. In November, 1896, a small amount of fecal matter still escaped from the fistula, and another attempt was made to close the latter by extended dissection, but it again proved ineffectual. In December, 1896, the abdomen was reopened and the transverse colon divided immediately before the implantation, and both its ends were closed with sutures. Thus six inches, ileum, the ascending and half of the transverse colon, had been completely excluded from the fecal circulation, but a large fistula, from which the mucous membrane protruded, still remained in the right iliac region. During the following six months the patient suffered much annoyance, not so much from the small amount of mucous discharge, as from the increasing prolapse of the posterior intestinal wall, which no apparatus could effectively reduce and retain. In August, 1897, I therefore dissected the opening in the intestine from its surroundings, and closed it by sutures in several layers. Primary union resulted. Thus about two and a half feet of small and large intestine were completely occluded, and have remained so, for a year and eight months, without causing the slightest inconvenience to the patient, who follows his profession as a barber. An examination in April, 1899, revealed nothing that might be construed in the light of an accumulation of secretions within the occluded loop.

In four of the above cases it seems that no untoward symptoms followed complete occlusion. The case of Friele cannot be considered in the discussion of the subject, as the unfortunate issue from causes which were not connected with the occlusion followed within seventy-six days of the operation. That so short a period of physical well-being is of no weight in the consideration of this question, is amply demonstrated by the results of experiments on animals. Baracz, the latest investigator in this line, who experimented on large dogs, found the occluded loops distended and filled with a large amount of semifluid, offensive matter, resembling meconium, as late as four hundred and twenty-five and four hundred and fifty-two days after operation. It is perhaps interesting to mention, in this connection, some other results of his experiments. One-third of his animals died of strangulation of the intestine within the opening made in the mesocolon. Another third, after a time, ranging from fifty-five to one hundred and seventy-eight days, of ulceration in the walls of the occluded intestine and consecutive peritonitis, or as the result of a bursting of one of the sutured ends of the occluded loop; others, of peritoneal infection during operation. And only two out of seventeen dogs lived, as above stated, for over a year, and were then killed. These experiments, it seems, certainly prove, beyond protest, that after a long period conditions may be present, or may develop within the occluded loop, that are a distinct menace to life itself. Such was the case with Obalinski's patient, in whom a second tumor began to form in the right half of the abdominal cavity twenty months after occlusion was done, finally necessitating removal of the loop three years after occlusion. I do not think, however, that Baracz's criticism of Obalinski's conclusions is quite fair. The latter distinctly states that the lesion was tuberculous, and, even if we may accept that an occluded loop is a "locus minoris resistentiæ" in a tuberculous individual, the late development of specific changes in the occluded portion in Obalinski's case cannot be adduced as proof of the dangers of occlusion of a normal segment of intestine. I am therefore inclined, with Obalinski, to regard his case as showing that occlusion can be practised with impunity on the living human being. We have, therefore, five cases in which no disturbances followed complete occlusion (Baracz, Obalinski, Wiesinger, Parkhill, Kammerer). In two of these (Obalinski, Wiesinger) complete occlusion was done upon the large intestine only; in one (Parkhill) on the small intestine; and in the remaining two (Baracz, Kammerer) the occluded portion was made up of small and large intestine. The operation of complete occlusion was done in two cases (Baracz and Obalinski) upon an intestine which, up to that time, had functionated normally. In the remaining three cases (Wiesinger, Parkhill, and Kammerer) other operations (colostomy, complete exclusion with open ends, unilateral exclusion) had been previously done. The intestine had thus been relieved of its function during a varying length of time before it was entirely shut off. The length of the occluded portion is another point of interest. Baracz operated for an ileo-cæcal invagination, shutting off the cæcum and that part of the ileum which was invaginated into it; Obalinski occluded the greater part of the ascending colon; Wiesinger, part of the transverse, the descending colon, and the sigmoid flexure. In Parkhill's case the length of the occluded portion remained unknown; and in my own, six inches of ileum, the ascending, and half of the transverse colon were occluded.

It seems to me that immediate complete occlusion at the first operation is not advisable. In one of the two cases in which this was done (Baracz), severe symptoms of peritoneal irritation, lasting three days, were noted, which finally subsided and gave no further trouble. In a third case, in which complete occlusion was attempted,[1] the symptoms which developed on the third day were so severe that the fistula had to be reopened, and remained so thereafter. In the three cases (Wiesinger, Parkhill, and Kammerer) in which the segment of bowel had been withdrawn from the intestinal circulation for some time before complete occlusion, no alarming symptoms followed the latter. I certainly think this plan should always be adopted. Sufficient clinical and experimental proof has been given that portions of the intestine through which the intestinal current does not pass, provided they are supplied with an outlet, will undergo atrophy. The secretion in them will become gradually less, and no doubt the nature of their contents will change from a very infectious material to one of much less virulence. Baracz, in his experiments on dogs, always thoroughly cleansed the loop before occluding it, and he believes that the amount of secretion and the number of pathogenic bacteria (coli communis) within the loop are in relation to the degree of disinfection which we have been able to obtain. As irrigation of the loop is accompanied by much risk of peritoneal infection, it would be wiser, in the human being, to rely upon a certain degree of disinfection, by following the plan suggested above, and not completely occluding at the first operation.

It is generally assumed that the mucous membrane of the small intestine secretes a larger amount than that of the larger intestine; in fact, that absorption is rather the rule in the latter. Clinical experience with intestinal exclusion does not seem to bear out this opinion, as a greater amount of secretion was observed to issue from the fistulous opening when the large intestine was involved. In my own case of complete exclusion mentioned at the beginning of this article, in which more than four feet of the small intestine and about two feet of the large intestine were involved, there has been very little secretion from the fistula. Indeed, I should say the quantity has been no greater than in my other case, where the ascending and part of the transverse colon were also excluded, but only six inches of the small intestine. Other cases of complete exclusion are reported, without occlusion of equal portions of the large and small gut, in some of which the secretion from the fistulæ was abun-

[1] Funke: Prag. med. Wochenschrift, 1895, No 32.

dant, in others almost *nil*. The amount of irritation that the mucous membrane is subjected to will determine the quantity secreted, rather than the fact that in one case the large intestine, and in another the small intestine, is excluded.

My own experience with fecal fistula in the ileocæcal region is limited to four cases. In all of them I have implanted the ileum into the transverse colon with Murphy's button. I have in the last two operations adopted the suggestion of Carle and Fantino,[1] of making an incision into the colon just large enough to force into its lumen one-half of the button, and then closing the incision with one or two sutures on each side of the cylinder. If these sutures are symmetrically placed on both sides, *i.e.*, if the cylinder of the button occupies the central portion of the original incision, it will be seen that on relaxing the intestine the entire line of suture will lie within the compressing edge. Naturally, in end-to-side anastomosis, this method of applying the button cannot be employed at the cut end of the ileum, where a purse-string suture must be used. But I have also resorted to it in three cases of posterior gastro-enterostomy, in one case of colo-colostomy (lateral approximation), in one case of cholecystenterostomy, and have been very much pleased with the modification. All these patients did well, with the exception of the last, who died on the fourth day, and here the button was found *in situ* and the approximation perfect. The method has some advantages over the original one of Murphy. There is no puckering of the intestinal walls, as when the purse-string suture is used, and, in consequence, when the button is closed the peritoneal surfaces are everywhere in perfect contact. There is, therefore, no need of reinforcing sutures, and I have not employed them in any of the above-mentioned cases. Care should, however, be taken to have no tension on the viscera when approximating the two halves, as in this way the incisions will always lie within the constricting edges of the button, and a larger portion of the intestinal walls will be included, thus perhaps insuring a larger opening after the button has passed.

I am somewhat surprised at the amount of contraction of the anastomotic opening in Parkhill's case, in which implantation of the ileum into the colon was done with the button, exactly as in my cases, although only one and a half months had intervened betweeen the passing of the button and the examination of the opening. In two of my cases, in which, after a lapse of nine and fifteen months, I thoroughly inspected the site of the former implantation, the most ideal union had, as I have already stated, taken place. There were no contraction and no formation of cicatricial tissue, not even a line to indicate that artificial union had been here established. I have also lately heard from my first case of fecal fistula, that of a lad, aged eighteen years,[2] whom I succeeded in relieving by unilateral exclusion, the ileum being implanted into the transverse colon. This operation was done four years ago, but no symptoms have developed which could be construed in the sense of a contraction at the site of the implantation. He has written me, only a short time ago, that he feels as strong as he ever did, and that the fistula has never again opened after it was closed three and a half years ago. I desire to make this statement here, to show that unilateral exclusion may effect a cure of fecal fistula, and, if it is successful, it is certainly the simplest and best plan of treatment.

It is interesting to note that the exclusion of more than six feet of intestine was not detrimental to the general condition of my patient. I believe this is the longest segment of bowel that has ever been completely excluded. This patient gained fifty to sixty pounds in the first year after unilateral exclusion, and after complete exclusion added another six pounds to his weight. Although he had considerable difficulty in regulating his bowels at first, they being very loose, after a time a certain accommodation to changed conditions seemed to occur, and his evacuations became normal.

It is difficult, even with the considerable number of clinical and experimental publications at our disposal, to formulate definite rules for surgical interference in these cases. Some points, however, can be well taken. We may state at the outset that a diseased portion of intestine should never be completely occluded. An escape for secretions must always be established here. This can be accomplished either by a simple lateral anastomosis (preferably without Murphy's button), or by a complete exclusion, followed by implantation of one or both open ends into the abdominal walls. Which of these methods should be employed must rest, in individual cases, with the surgeon. When it seems desirable to avoid all irritation from the passage of intestinal contents over a diseased area, complete exclusion is preferable; but when this seems unnecessary, a lateral anastomosis, as the simpler operation, deserves consideration. It is well to recall, in this connection, that now and then apparently inoperable tumors of inflammatory origin can later on be removed, when complete exclusion has been previously done. This is due to a decrease in size of the tumor after removal of the source of irritation. Is complete occlusion justifiable on the normal healthy intestine primarily? I would say, "No." The dangers which are likely to attend this procedure are too great, and the necessity for doing this operation primarily does not exist. It is regrettable that all experimental work should have taken this direction, and that the question of secondary complete occlusion, after primary exclusion, should not have received some attention. That the latter is a much safer procedure, we may, I think, assume without prejudice, in view of the degenerative changes that occur in those portions of the intestinal canal that have ceased to functionate for some time. The risks entailed in final complete occlusion, when some point of the loop is adherent to the abdominal wall, are small under the conditions just stated, and are certainly outweighed by the advantages to the patient, who has been rid of his fistula, a continual source of bodily and mental irritation.

## A GROOVED PERINEAL CANNULA TO BE USED AS A GUIDE IN PERFORMING PERINEAL SECTIONS IN CASES OF URETHRAL OBSTRUCTION.[1]

BY RAMON GUITÉRAS M D.

NEW YORK

Two years ago I presented before the section of genito-urinary surgery of the New York Academy of Medicine an instrument called a perineal guide, to be used in cases of complete urethral obstruction due to whatsoever cause, for the purpose of establishing a direct communication with the posterior urethra and neck of the bladder by the way of the perineum when it is necessary to perform a perineal section, thus avoiding the necessity of stabbing about in the dark as in Cock's operation.

The first instrument was rather primitive, as is usually the case when one is trying to originate a new operative procedure. It showed me, however, that such an instrument had a place in genito-urinary surgery, and was an important one in a certain variety of

[1] Presented before the Society of the Alumni of the Charity Hospital at the December meeting 1898

difficult cases. It was constructed on the lines of an ordinary cannula and stylet, excepting that there was a groove running along the upper surface of the cannula and that there was a handle attached to the end of the stylet. The cannula was two and three-quarters inches long, and corresponded in size to a No. 6 sound, French scale. The stylet was No. 3 of the same scale, which measurement also represented the size of the lumen of the cannula through which it passed. The handle attached to the proximal end of the stylet was one and one-half inches long and flattened laterally.

With this instrument I punctured a number of bladders through the perineum on the cadavers used in teaching the genito-urinary operations at the Post-Graduate Medical School, and I also had an opportunity to try it in a difficult case on the living subject, in which one of my colleagues had begun to despair of entering the bladder by the perineal route. This experience proved to me that, although it was an instrument of decided value, there was still room for improvement.

The faults apparent were: First, the groove was not deep enough to allow the knife to be under good control. Second, the lumen of the cannula was too small to allow the urine to escape freely. Third, the handle of the instrument should be attached to the cannula rather than to the stylet, and should be flattened antero-posteriorly in order to be under good control after the stylet has been withdrawn and while the knife is being pushed along it.

I therefore modified the instrument, correcting the faults above mentioned, and exhibited it before the New York Genito-Urinary and Dermatological Society, and an illustrated description of it was published in the May, 1897, number of the New York *Journal of Cutaneous and Genito-Urinary Diseases.*

The modification proved to be a great improvement on the former instrument, but it was not quite long enough to tap the posterior urethra and bladder in cases in which there was an unusual amount of thickening in the perineum. This led me to increase its length until at present it has the following dimensions (see cut): Cannula, four and one-quarter inches long; handle, two and one-half inches long; trocar, four and three-quarters inches. This will, I think, prove to be sufficiently long to penetrate any perineum in spite of extreme thickening, whether due to fat, inflammatory exudate, or extravasation of blood or urine.

A number of my colleagues who work in the same line of surgery seemed to think at the time that such

Fig. 1.

an instrument was not necessary, and that it was a comparatively easy matter to perform a perineal section without a guide. I have been exceedingly gratified, however, to learn that since then many of them have procured the instrument and have been very much aided by it in difficult cases. Personally I have on several occasions had extreme difficulty in cutting into the posterior urethra by the perineal route on account of excessive hemorrhage, extensive perineal infiltration, or in cases of collapsed bladders, and I have also at times cut the perineum more than I cared to, besides spending more time over the operation than I thought the condition of the patient's kidneys warranted.

I know that other surgeons are at times puzzled when working in a dark and bleeding perineum in which the landmarks are obscured, and I was at one time

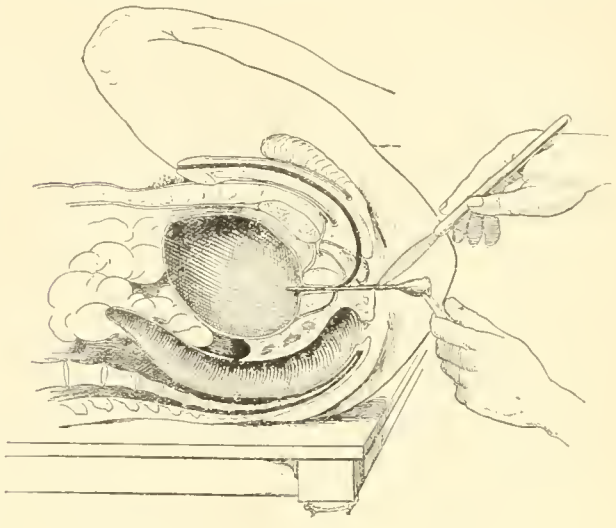

Fig. 2.

present at an operation where Europe's greatest surgeon found himself hopelessly lost in doing a perineal section, and was obliged to quit the perineum and enter by the suprapubic route in order to pass a guide from the bladder through the internal meatus into the urethra, upon which he could cut. If, then, it is difficult for experienced surgeons with well-trained assistants and perfect hospital equipment to perform a perineal section without a guide, it is easy to see how much harder it is for a country practitioner in an out-of-the-way place, aided only by local assistants from the laity. It is therefore to those men that an instrument of this kind is most important. They need it and will be aided by it.

I will accordingly proceed to enumerate some of the cases in which such an operation is indicated, and to explain the technique that should be employed in performing it. (1) Cases of impermeable stricture with retention, in which an immediate radical operation is demanded. (2) Cases of ruptured urethra. (3) Cases of extravasation of urine. (4) Cases of extensive urinary abscess. (5) Cases of perineal cellulitis. (6) Fracture of the pelvic bones with pressure upon the urethra.

Of course, it is understood that in all these cases no guide can be passed through the urethra into the bladder.

The technique of the operation is as follows: The patient must be in the lithotomy position. As, when this operation is indicated, a guide cannot be passed through the entire urethra, a filiform should be inserted as far as it will go, which is generally into the perineal urethra, and then a tunnelled sound should be passed down over it. After this an incision is to be made in the median line from just behind the scrotum to within three-quarters of an inch of the anus, in the direction of the membranous urethra, care being taken to avoid wounding the bulb. If the end of the urethral guide is in the perineal portion of the urethra, the surgeon should cut down upon it and catch the walls of the canal on either side by artery forceps or by ligatures,

so as to hold it open on the stretch. If a stricture is present, he engages the point of the knife in it and then cuts down through the obstruction by a rapid stroke.

If not successful in cutting through the stricture in this way then the instrument that I have described, must be used as follows: After inserting the forefinger of the left hand into the rectum until its tip rests upon the apex of the prostate, the surgeon should introduce the perineal cannula held in the right hand, with the thumb pressing down upon the proximal end of the stylet, through the incision in the perineum, and push it steadily inward and downward in the median line until it is felt to have passed the tip of the forefinger in the rectum. It is then probably in the prostatic urethra. One of the assistants should then grasp the end of the stylet and withdraw it. If urine escapes through the cannula, we know that we have entered the prostatic urethra or the neck of the bladder, and are therefore in the desired locality. If no urine escapes, the instrument is to be pushed in a little farther until it has been introduced to the point where urine escapes through the cannula on the withdrawal of the stylet. The finger should then be withdrawn from the rectum and the handle grasped firmly in the left hand; the blade of a knife held in the right hand, with the cutting edge upward, should be pushed along the groove on the top of the instrument into the bladder. When the knife blade is withdrawn, a grooved director is to be passed along the cannula in the same way, after which the instrument can be withdrawn. The assistants must be instructed to hold the urethra open by means of the forceps or traction sutures placed on either side of it while the operator cuts through the entire stricture from its distal to its proximal end, and the urethra is free to the prostatic portion.

In case there is a urinary abscess, or an extravasation in the perineum, which compresses the urethra, the incision through this inflammatory tissue may reduce the obstruction sufficiently to allow sounds to pass readily through the urethra.

The important point in the operation is that in inserting this instrument it must be remembered that it should not always be pushed in horizontally, as in this case there is often danger of its going into Retzius' space in front of the neck of the bladder. It should generally be pushed backward and somewhat downward. When the end of the instrument passes the tip of the finger on the apex of the prostate, it may then be in the prostatic urethra. If this is the case, the blunt end can be easily pushed through into the bladder. In some cases, however, the instrument when it passes the tip of the finger does not enter and remain in the free lumen of the prostatic urethra, but passes through it and then through the anterior wall of the prostate into the bladder. It is therefore wise, after passing the apex of the prostate, to slip the finger along over the base of the gland, and then to push the instrument toward the finger tip in this new position until one is conscious that the tip of the instrument is in close proximity to the end of the finger, in which case he can be pretty sure that it is in the bladder, and can consequently draw out the stylet and allow the urine to escape. The blunt point of the cannula can then be pushed against the end of the finger, thus showing the operator exactly where he is before the incision is made. At times the wall of the prostate gland or the sphincter vesicæ muscle is cut, but this is liable to happen in the case of any operation, even when a guide has been passed through the urethra into the bladder from the meatus.

The after-treatment is the same as in any case of perineal section, *i.e.*, a perineal tube should be inserted into the bladder and siphon drainage maintained for from four to fourteen days, during which period sounds should be passed at intervals of forty-eight hours.

This instrument may be also used for a number of other purposes, as for exploring a suspected prostatic abscess; or for the puncture of an abscess in the vault of the vagina, in which case if pus escapes, a knife could be inserted into the abscess cavity along the groove on its upper surface, with an exactness which we could not obtain by any other means. It can be used for tapping a hydrocele, for abdominal paracentesis, or for tapping the bladder suprapubically, in which latter case it could be tied in if so desired, or an incision could be rapidly made along it of sufficient size to allow a good-sized catheter to be pushed through into the bladder. There are many other operative procedures in which this instrument would prove of inestimable value, and I feel in presenting it to you that it is one which can be of use both to the surgeon and to the general practitioner.

23 West Fifty-third Street.

---

## THE ILL EFFECTS OF THE ROENTGEN RAYS AS DEMONSTRATED IN A CASE HEREWITH REPORTED.[1]

By DAISY M. ORLEMAN, M.S., M.D.,

resident physician, peekskill military academy, peekskill, n. y.

Having just recovered from a severe injury of ten months' duration resulting from the application of the Roentgen rays, I desire to place the case on record. It is important to bring such cases to the knowledge of the medical profession, because an aggregation of the observed appearances in each case can thus be made, a mode of treatment adopted, and further accidents may possibly be prevented. A limited knowledge only is apparently possessed by the average surgeon and physician regarding the successful treatment of such a wound, in consideration of the fact that so large a number of patients are daily exposed to the use of the *x*-rays.

I had just recovered from an oblique fracture of the left femur, about six inches above the knee. At the request of one of the attending surgeons, the *x*-rays were applied. The first exposure was made in January, 1898. It was unsuccessful, and a second one was made in March with a similar result. A third exposure was made on May 14th. No discomfort during the previous exposures was felt, but on this occasion a slight tingling sensation was experienced. This exposure, too, was unsuccessful.

If a necessity had existed for the application of the *x*-rays, I might have borne the unfavorable result with greater resignation, but as no impaired function existed, and by ordinary methods of examination the limb seemed in perfect condition, it was reasonable to conclude that there was a normal approximation of the fragments.

The Edison apparatus was employed. Spark length, eight inches; voltage, 110; egg-shaped tube, about six inches from terminal to terminal. Distance of the tube from limb, ten inches; interval between first and second exposures, six weeks; between second and third exposures, eight weeks; duration of each exposure, seven minutes; position of tube, directly above and parallel to limb; anode, nearest knee.

From the reported cases which I have read, I find that the period of incubation between exposure and appearance of symptoms is usually ten to twelve days. In my case I did not observe anything until twenty-one days later, when the first appearance of inflammation occurred, covering an area of about an inch, which caused some itching. Day after day this itching continued and the area increased in size. The redness

[1] Read before the Medical Faculty of the County of Westchester, N. Y., May 17, 1899.

partly disappeared on pressure. Alcohol was applied for the itching, which rendered immediate relief, but the symptom returned soon after. The area covered four inches in the form of a dermatitis, when an ointment of boracic acid was applied, and it was not until then that I realized I was the victim of an x-ray injury.

Numerous small infiltrations differing in size appeared, which were separated by portions of reddish infiltrated skin, that within a few days became confluent and formed several large blisters, such as appear after scalds. Upon opening these, serum exuded from each one. The outpour of serum, which was quite annoying, continued for several days, and was followed by the denudation of the superficial layer of skin, leaving an exposed surface very painful to the touch. The boracic-acid ointment was continued, followed by balsam of Peru and castor oil, ten per cent.

After repeated attempts to endure the latter application, owing to the severity of the pain that it caused I discontinued its use. The surface was bathed daily with a solution of bichloride (1 : 1,000), and a dressing of boracic-acid ointment was applied. Early in July—several weeks later—pain commenced to be felt at occasional intervals, which continued to increase in severity. Lead and opium wash followed by an ointment of zinc and lanolin was applied daily for several weeks. The entire denuded surface became covered with a false membrane, which gradually increased in thickness, and soon the central portion of the lesion presented an open ulcer. Ichthyol ointment was applied, and balsam of Peru in castor oil was again tried with no success. The area was bathed in an antiseptic solution daily and a soft dressing applied.

During the early part of August, the paroxysms of pain became more frequent, and often interrupted sleep at night. At such times, compresses dipped in a cold solution of bichloride afforded temporary relief. The use of the hot bath was suggested to me, and, as the limb could easily be submerged in hot water, several repeated trials were given it with no apparent lessening of the pain. Occasionally, the burning pain at such times became almost unbearable. A tough yellowish membrane formed in the centre of the ulcer that extended to some depth, the superficial surface of which appeared soft. The peculiar excruciating pain increased, rendering sleep at night almost impossible. This, combined with the fact that the lesion showed no prospect of healing, regardless of the applications thus far applied, led me, on August 24th, to consult a dermatologist of Boston, as I was at this time visiting at North Cohasset. The affected area was washed in peroxide of hydrogen, and nitrate of silver was applied At night an ointment of resinol was used, and in the morning the area was bathed in hydrogen peroxide, and aristol was then applied. This treatment was continued for several weeks, nitrate of silver being used about once in five days. Owing to a defective state of my general health, a tonic of iron, quinine, and strychnine was ordered. It was advised that I remain in bed for several weeks, which injunction I did not then obey. The pain did not subside, and in order to obtain several hours of uninterrupted sleep I was obliged to resort to the use of morphine at least once in three days.

Upon my return to New York, I consulted Dr. W. T. Bull, who examined the wound and recommended a system of poulticing in order to remove the slough. This was continued for several weeks, but on account of the intense pain which the application of each poultice produced, the use of the poultice was discontinued. Having practically exhausted the list of possible applications, it was deemed advisable to remove the sloughing area by operation. This was accordingly performed by Dr. Bull early in October. An elliptical incision of about three inches in length extending in depth to the fascia was made; the affected tissue was removed and the parts were approximated by stitches. This was done under a local anæsthetic (cocaine). I remained in bed two weeks, at the end of which time the tissues were not thoroughly united, but the application of an aristol dressing was recommended, and the wound to be bathed in a solution of bichloride of mercury daily. Instead of the wound healing, it grew worse, and, in spite of daily dressings, gradually commenced to assume an appearance of sloughing. The pain increased to such an extent that it seemed almost unendurable. Heat was applied, also boracic-acid ointment, and as no relief to the continued pain was afforded, cocaine, four-per-cent. solution, was tried, which gave but temporary relief. A solution of cocaine and carbolic acid, when the pain was severe also red wash (sulphate of zinc and compound spirits of lavender water), was recommended, and was used for two weeks with no apparent success. Cocaine soon lost its soothing effect and eucaine was used, and in order to obtain relief from the incessant pain I found it necessary to increase the strength of the cocaine and carbolic solution to such an extent that there was danger of destroying the vitality of the tissues. These local anæsthetics modified the pain and diminished the frequency of the paroxysms more than anything thus far used. The surface of the wound was not, however, particularly sensitive, hence the effect of the anæsthetics was lessened. Orthoform ointment (one drachm to one ounce) was also applied without effect.

About this time—Thanksgiving Day—I visited in Boston, and was, therefore, advised by Dr. Bull to consult a surgeon there. Accordingly I consulted Dr. H. L. Burrell, who examined the ulcer carefully and said he believed he could effect a cure within three months, provided I would consent to remain in bed during the greater part of that time. I remained in Boston and placed myself under the treatment of Dr. Burrell at the Boston City Hospital. The ulcer was then three and one-quarter by two and three-quarters inches, covered by a thin, grayish slough one-thirty-second to one-sixteenth of an inch in depth. The ulceration was excavated, the edges of the wound were purple, and the cyanosis extended out a considerable distance, around which were numerous blebs. It was clear that no separation was taking place, and that further tissue necrosis, even to the point of gangrene, was imminent. An area of anæsthesia surrounded the wound and extended almost to the knee.

Dr. W. N. Bullard, a neurologist of Boston, was called to examine the wound, and stated that the underlying condition was a destruction of the terminal nerve fibres—a state of atrophic neurosis. The pain, of an intense, burning character, was excruciating, and a liberal quantity of cocaine combined with a strong solution of carbolic acid failed to give relief.

Dr. Burrell's treatment, beginning December 3d was as follows: Absolute rest in bed, with the adjustment of a splint under the leg; application of flaxseed poultices every three hours day and night, when they were varied with compresses of chlorinated-soda wash (1 : 16). Sufficient opium combined with calomel was given to control the pain; at first one grain of opium and one-sixth to one-fourth grain of calomel every three or four hours as occasion demanded. As the rest in bed, in conjunction with this form of treatment, continued, the congestion and hyperæmia diminished. Strychnine, one-sixtieth grain three times a day, was taken from this time until my recovery.

Within ten days the sloughing was removed to a considerable extent—a slough of only about one-half

an inch in width, at this time, remaining about the edges. New granulation tissue was beginning to form. Compresses of chlorinated-soda wash were then applied during the day, and flaxseed poultices at night. Twenty days later (December 2d) tincture of myrrh (1 : 20) was tried, but it did not appear to clean the surface as well as chlorinated soda. On December 25th, the first skin graft, a small piece of skin, was made, and a one-fourth of one per cent. solution of boracic acid was applied; the wound was kept constantly moistened with this solution. On January 1st, a second skin grafting, of several small pieces of skin, was made. On January 9th, the boracic-acid solution was changed, and a dry dressing of aristol was applied, which remained until January 15th, when the wound was thoroughly irrigated with a saturated solution of boracic acid; compresses and irrigation with tincture of myrrh (1 : 8) were used at regular intervals for several days. On January 22d, the fourth and last skin grafting of eight small portions of skin was made, and compresses of boracic acid were constantly applied. The grafting was interesting in that the grafts took in the midst of sloughing tissue.

I was allowed to sit up during the latter part of January, but was not permitted to lower the affected limb, and kept it in a horizontal position until the skin entirely covered the wound. The mildest lotions were used, of which the least harmful was boracic acid At one time, a wash of nitric acid (1 . 128) was used in order to hasten the process of the separation of the slough, but within eight hours pain was experienced and the granulations grew fainter. If the wash had been continued, the granulation tissue would no doubt have been destroyed. I first attempted to walk on February 15th, when skin entirely covered the wound. A dressing of aristol was continued one week longer. A heavy scab formed which disappeared six weeks later.

A microscopic examination of a section of the tissue removed by the operation in October indicates a chronic inflammation characterized by the development of dense fibrous tissue in abundance. Infiltration of leucocytes in small numbers is seen throughout the fibrous tissue and in the subcutaneous adipose tissue. The blood-vessel walls generally thicken and the lumina is narrowed as a result of the thickening of the intima. The base of the ulcer is lined by a thin layer of necrotic tissue which joins rather abruptly the underlying fibrous tissue.

The following is taken from Monell's "Manual of Static Electricity": "None of the alleged injurious effects of *x*-rays reported hastily and with more or less sensation are caused by the static current. It seems wellnigh impossible that alopecia and dermatitis should be attributed to *x*-rays by practical medical observers, but as they have been so attributed, the simple fact may here be stated, that these electrical or heat effects, which resemble sunburn, result from the action of heavy currents operating large coils, and are not due to *x*-rays. Roentgen's classical report contained the statement 'the rays have no calorific effects'; and I am not aware that any one has yet shown Roentgen to be mistaken, and the static current is not electrolytic."

Dr. F. H. Williams, of Boston, was asked by Dr. Burrell to examine my wound. He states that the following precautions should be taken to avoid any harmful effects from the *x*-rays from either a static machine or a coil as an exciter: First, never have the tube near the patient; it should be two or three feet away when using the fluorescent screen, and should be three feet or more from the plate when taking *x*-ray photographs: Second, between the patient and the Crookes tube there should always be interposed, as suggested by Tesla, a thin screen of aluminum, which should be grounded by connecting it to the gas-pipe with a proper wire. He said that during the past three years he has made between two and three thousand examinations and no burn has occurred, and that his experience in treating *x*-ray burns, so called, have been limited to patients who have burned themselves as an experiment or to patients seen in consultation. In treating these burns he says it is of the first importance to realize that the local treatment is entirely secondary to a general treatment devoted to promoting the nutrition of the affected part.

Numerous cases of Roentgen-ray dermatitis are on record, all of which differ in severity and duration. Several cases are reported in the Transactions of the Medical Society of the District of Columbia for 1897, one of which describes a severe case that at the end of six months had not healed and had then passed from the observation of the physician. One case is on record in which the false membrane which had formed was curetted and resulted in the formation of an indolent ulcer. Another case has been reported in which skin grafting was tried with no benefit. I believe that in these cases skin grafting will prove effectual if performed at the time when the wound has been brought to a proper condition to receive the new skin.

In the treatment of such an injury it is essential strictly to observe the therapeutic value of local rest. Had I given this precedence in the beginning, when I found that the case was not proceeding satisfactorily after the due application of poultices and stimulating washes, under which there was no local evidence of repair and the wound remained stationary, I might have had a more speedy recovery. There were obviously two requisites in the treatment which effected the cure in addition to the local applications: viz., to overcome the pain and to maintain the limb in a perfect state of rest. I found massage of the limb during the latter part of the treatment, twice daily, to be of inestimable value in maintaining good circulation.

## CYSTOSCOPY AND URETERAL CATHETERIZATION IN WOMEN.[1]

By EDWARD NICHOLAS LIELL, M.D.,

JACKSONVILLE, FLA.,

FORMERLY LECTURER ON DISEASES OF WOMEN, NEW YORK POLYCLINIC, AND VISITING SURGEON, ST. ELIZABETH'S HOSPITAL, NEW YORK; MEMBER OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK AND FLORIDA STATE MEDICAL ASSOCIATIN.

Cystoscopy is a subject that has but recently come in for a fair share of deserved attention, its relation to bladder and ureteral, as also to renal, conditions, being of importance alike to the general practitioner and the surgeon. The researches of Pawlik, Bozeman, Kelly, Reynolds, and others have shed new light and added greatly to our knowledge as to diagnosis and treatment of diseases involving the bladder, ureter, and pelvis of the kidney. In addition to direct inspection, it offers at the same time a ready means of direct medication, thus opening up a new field in the treatment of bladder disease. To Howard Kelly, of Baltimore, we are indebted for this procedure.

It is perhaps needless to state that exploration of both bladder and ureter should be attended with due care and caution, thorough asepsis being observed, as in any surgical procedure. Before and subsequent to using the cystoscope I always irrigate the bladder with a mild antiseptic solution, preferring either boric acid or Thiersch's solution. Regarding an anæsthetic, when the urethra is tolerant and of large calibre, cocaine anæsthesia serves an excellent purpose In the

[1] Read at the twenty-sixth annual meeting of the Florida State Medical Association, held at Jacksonville, Fla., April 19 and 20, 1899.

majority of cases, however, general anæsthesia will be necessary. Under favorable conditions, though infrequently, exploration of the bladder may be undertaken in one's consulting-room, allowing, however, several hours for rest subsequent thereto. The patient may be made to assume either the knee-chest or the Trendelenburg position, the former being preferable, as in consequence of diminished abdominal pressure the bladder becomes partly distended with air upon withdrawal of the obturator from the cystoscope. Illumination is derived from an electric light, with head reflector, and inspection of the bladder can be made at one's will and every accessible portion shown, the position of the speculum being changed from place to place.

The cystoscope readily demonstrates the condition of the interior of and the walls of the bladder, the ureteral orifices being recognized by the characteristic appearance of the slit or the slight eminence usually in the mucous membrane at either side. The ureters are elastic and have loose connections, the catheter determining their calibre and the existence of obstruction and kinking. With preliminary training and personal skill as prerequisites, little difficulty will be encountered in arriving at positive visual diagnosis.

By catheterization of the ureters much obscurity in surgical renal disease may be cleared up, the character of the urine obtained affording one an opportunity of making a more or less positive diagnosis as to the condition of the renal pelvis. The ureteral orifice may be displaced, or in a measure occluded when there exists a thickening of the wall of the bladder, some difficulty then being met with in locating or entering it. To obviate this, staining the urine, as suggested by Fenwick, of London, is of great service. One and one-half grains of fuchsin given to the patient an hour or two before the examination will color the urine a delicate pink, which may be seen to issue from the orifices of the ureters.

Garceau, of Boston, has recently brought out a simple device in the nature of a vaginal depressor, fastened by a screw to a Kelly cystoscope, by which means the ureters may be readily catheterized in the knee-chest position, the cystoscope being held in a horizontal plane and the ureteral orifices presenting opposite the vesical end of the cystoscope when turned about forty-five degrees to one side or the other.

In the case of the bladder, the cystoscope affords information as to the presence of diffuse redness or hyperæmia, with consequent catarrhal conditions; hypertrophied walls, with corrugated mucous membrane and thus diminished calibre; pathological growths, as tuberculous, papillomatous, cancerous, etc.; pyelitis, calculi, foreign bodies, etc. In ureteritis, there is usually shown an alteration in the appearance of the ureteral orifice and in the mucous membrane of the bladder adjacent thereto, the tissues being inflamed and of an angry red. In this connection I would say that uric-acid crystals and free oxalates, the result of imperfect metabolism, act as irritants in its etiology. Acute ureteritis may be mistaken for renal or intestinal colic, appendicitis, and salpingitis, it being differentiated from these in that, beginning in the region of the kidney, the pain steadily takes a direction downward and inward toward the bladder, tenderness along the line of pain being also evident. The chronic form takes upon itself a frequency of micturition, associated with a bearing-down pain, both aggravated by standing or exercise and markedly relieved by the recumbent position.

A differential diagnosis as to pyonephrosis and pyelocystitis can also, in many instances, be made, a case of pyonephrosis and catheter drainage, recently recorded by Reynolds, of Boston, furnishing an example of the value and limitations of the ureteral catheter, the kidney being irrigated with decinormal salt solution, and the catheter being fastened in position and retained for a period of seventeen days. Reynolds, who has done considerable work in the line of cystoscopy and catheterization of the ureters in women, states that in the surgery of the kidneys, the study of the separated urines of the two kidneys takes the chief place, furnishing a method of physical examination of the kidney which is both accurate and safe, enabling one to isolate the disease and to determine with certainty which kidney is affected and the condition of each. In a similar manner, a diagnosis of tuberculosis of the kidney may be arrived at through examination of the urine for tubercle bacilli. Regarding the question of possible ligation or injury of the ureters in the course of surgical operations on the abdominal or pelvic viscera, cystoscopy and ureteral catheterization offer a ready means of diagnosis.

In the case of a calculus situated in the lower third of the ureter, in females, its position being located either through cystoscopic, vaginal, or rectal examination, it can frequently be removed by incision through the vaginal vault, as witnessed by a case lately reported by Mundé, of New York, the calculus impacted in the left ureter being of interest in itself, in that it showed a groove on one side, which had evidently allowed the passage of urine and had prevented in great measure the kidney from becoming distended. The removal of the calculus, however, was followed by a gush of purulent urine.

Upon the diagnostic acumen of the physician or surgeon depends the ability to recognize symptoms, which demand careful consideration. An observer who has improved his opportunities but rarely falls by the wayside.

An experience of several years in the study of cystoscopy of the female bladder and ureters, impels me to state that it offers a large and increasing sphere of usefulness, opening up a ready means of differential diagnosis, consequent enlightened treatment, and positive results.

## HOW TO RETAIN YOUR GRIP ON THE PRACTICE OF MEDICINE.[1]

BY SIDNEY DAVIS M.D.

MILTON, PA.

SOME years ago, while riding with a physician in one of the cities of this State, he spoke of a certain doctor who at one time held a large practice in that city and gave it up. As his work was among fine families, and he himself was a refined, cultivated physician, I asked why he left the field. My friend replied that "from some strange cause he began losing his grip on his practice." After I separated from this friend his words came back to me, "From some strange cause he began losing his grip"; and then I wondered how a man could lose a grip after once securing it, particularly if he was not overtaken by old age or ill health. And the thought occurred, what a terrible thing it was after the long struggle of securing a grip to lose it "from some strange cause." My mind is perfectly satisfied now that it is a very easy matter for a physician to lose his grip on the practice of medicine. Whether you will agree with my views on this subject is another affair. One proposition you will all approve, and that is, to retain a grip it is highly necessary first to secure the grip. To start with a right foundation, a sound moral character should come foremost above everything else. I do not

[1] Address of the retiring president at the fiftieth anniversary of the Lycoming County Medical Society, at Williamsport, Pa., April 14, 1899.

care if a doctor has the brains of a Webster, if he is deficient morally he will positively fail to secure or retain a grip.

The prime mistake often made by young physicians is in locating. Men who are calculated for a village practice aspire to large towns, and those who would succeed well in a good-sized town enter the field of a city where they are brought into competition with numbers of eminent men, besides being handicapped with the dispensary service, the curse of the young city practitioner to-day. There is no place like a village for the recent graduate to settle. Here he will have time to sit down and examine himself, a very important point; then after some years he will have enough experience to decide whether he has ability to enter into a larger competition. And while he is doing this he might make the little arithmetical calculation that $6,000 in the city is not so much as $3,000 in a country town. I will grant him the privilege of making the second move on two conditions: the first is, that he must have a snug bank account; the next is, that he must make this change before he has too many gray hairs. The second one should be his last; if he makes a third, he is almost certainly a failure.

I will now give in one sentence why physicians fail to secure a grip, and why they are not able to retain a grip; and mark well the words. It is just this: they are not truly interested, and they are not willing to invest money in their profession. To prove this statement I will take up in order what Emerson would style the externals of a man, and then the internals. The first of the externals is the general appearance of a physician as regards his being neatly dressed, and, above all, clean. I once asked a lady of another town why she did not employ a certain physician of her home, whom I knew to be mentally superior to every other one in the place. She replied, "I cannot stand his black finger-nails." That settled the question. A medical man is supposed to be an antiseptic gentleman at all times, with faultless linen, and everything else to correspond. The next external that I regard as exceedingly important are his offices If a young physician were to ask what advice I would give to aid him on entering a town, I would say, have the finest offices your means will permit, and go on improving and freshening them up occasionally with a new picture and very often with a modern book, bearing in mind that there is nothing furnishes a house or office like books and pictures. I have entered the offices of specialists in the cities and have been surprised at the barren condition of their reception-rooms. Why they could not have their victims comfortable while waiting for their turn in an attractive room, I could not understand The next external I would touch upon is the physician's stable outfit. Now, some doctors may go to extremes in this direction and show a degree of extravagance in horses and conveyances that is unwarrantable. Still, where you find one of this kind, you will see twenty who move the other way, men who are satisfied to ride in any old tumble-down turn-out, only so they manage to get there.

Please bear in mind you are travelling before the public; and while there are numbers who do not care anything for these so-called externals, there are certain observers who do object and who attach importance to these matters, and make up their minds that it is just possible this or that physician is careless in everything. You are living in a fast age and a fast country, and in this race we are all running there is a possibility of your getting the flag before you are aware of it.

I will now pass to what would be termed the internals, and by these I mean just what trouble and expense you are willing to undertake in order to advance yourself and make your grip all the more secure by mental improvement. Every young man on leaving the halls of his university should resolve to come back to the city for instruction at least ten years after graduating. Ten years, and what it means! The tale is told whether you are going to be successful. The very fact of your seeking additional information proves that you are interested to the extent that you are willing to make the investment.

Ten years has brought about such a maturity in your mind that facts will be absorbed from an entirely different standpoint in comparison with early medical education. Young physicians are almost compelled to do this when it is known that there have been more rapid strides in the last twenty-five years than in the one hundred years preceding. Indeed, these advances are so rapid that he must be very wide awake to keep pace with them. He should lose no opportunity when it is possible to be thrown with other physicians, and this brings me to the important point of the medical society, and right here is shown how much true interest a man has in his profession. Show me leaders in medical societies and I will show you men who have large practices as a rule. One of the strangest things about the Lycoming County Medical Society is that at the regular monthly meetings the largest percentage of attendance is from the members outside the city of Williamsport with its sixty-odd physicians, one of the most inexcusable occurrences with their telephones at command to protect them, while the country physician has to take his chances Of course the explanation for this may be, that the poor country doctor probably needs the medical society more than the physicians of Williamsport do. I want to give you one note of warning: Remember, when you fail to respond to your name, as recorded on the yearly roster of the society, for a paper or discussion, you are simply retrograding and your grip is slackening.

If young men would pay attention to their medical society, with more painstaking work at the bedside instead of grasping at a lot of catch-straws, there would be more lasting results. I have spoken to you of freshening up your office with a new work, I now say, freshen your brain with new ideas. Remember there is magic in the words, being "up to date." Ridicule these things, laugh at them, but defy them if you dare, and I will tell you what will happen. You may possibly wake up some morning (if you ever do wake up) to the fact that a certain colleague of yours has gone up two rungs on the medical ladder and you have slipped two rungs; and this slipping was done imperceptibly to you, but very perceptibly to the public. Do not flatter yourself that it is possible to pull together suddenly. You have been allowing certain things and opportunities to go by default, which should be regarded as your fortifications. You have been neglectful of them and yourself to such an extent that your colleague has caught you napping. The practice of medicine is beset with dangers like everything else. You may any day be brought to face such a combination in your town as a young man with brains, ambition, and a certain amount of money thrown together in the same person, or you might have a young doctor drop down on you with another combination—brains and lots of genuine American get-up. The last qualification is something to be dreaded, as all the world knows by this time it stops at nothing. Therefore it behooves you to have yourself and everything else in trim. If you should be blessed with four qualifications which I regard as very essential, you can simply defy all young doctors and their combinations. They are these: fine nerve, excellent judgment, abundant resources, and the whole surrounded with a large supply of good nature.

Avoid allowing yourself to become old, remembering that there are old-young physicians and young-old

physicians. If you think some additions will improve your appearance as age advances, be sure to get them. Remember that "a few bricks to a broken chimney and a coat of paint on an old house improve its appearance wonderfully." There is one man to whom I want to say a word, and then I am through. It is to the man who has the grip, to the doctor who is on the flood tide of success, to the man who has apparently no grounds for fear. To that man I say, nothing is secure; riches have flown, and so has the practice of medicine. To make this clear I want to tell you what happened to one of the prominent physicians and surgeons of this State. This man, whose name I will not mention, had everything to insure him success—a large practice, family prestige, for he was descended from a line of physicians who had distinguished themselves in science so that the name is known to-day on both continents. This surgeon was called upon to perform an operation in an adjoining town, where he was constantly being summoned for consultations and operations. In this case he had the misfortune to have his patient die on the operating-table from the effects of the anæsthetic. The case created a great sensation at the time. After that he was seldom called to this town. In talking over this case with a friend of mine, a physician, he made this remark: "I made a reputation in forty years, and lost it in a day."

## FOREIGN BODIES IN THE THROAT.[1]

By HERBERT J. HOPKINS, M.D., C.M.

SEVERAL months ago Dr. Fulton presented a clinical case—a child with a foreign body in the lower air passages. I believe he said it was in one of the bronchi; that it had been there twenty-four hours. He had not operated, and the child was not suffering much. It was recommended that an expectant plan of treatment be followed. This was done, and three weeks later the foreign body was coughed up. Statistics show a mortality in these cases of about twenty-five per cent.; the remaining seventy-five per cent. recover. The different methods of treatment, operative or non-operative, do not seem to differ much as to the final aggregate results, thus showing that there are some cases best treated on the expectant plan, and others in which an operation is imperative. Cases arise, of course, in which an immediate operation, laryngotomy or tracheotomy, is absolutely necessary to save life. Summoned to a case of foreign body in the throat, there is very little time for meditation or preparation; it behooves us to know what to do and how to do it. While instant death may occur, in the vast majority of cases the alarming symptoms of spasmodic asphyxiation have subsided long before the arrival of the physician; and if the foreign body has not already been expelled, its deleterious influence is spent in causing a comparatively mild degree of discomfort; and plenty of time is allowed to ascertain from the history of the case the probable character of the foreign body, and the institution of a thorough and systematic examination to discover its exact location, after the discovery of which its removal is ordinarily a very easy matter.

Though the character of the foreign body, whether round, smooth, angular, pointed, small, or large, is a determining influence as to its place of lodgment, it is wise to explore systematically the whole tract till its discovery; and for this purpose it is most desirable to have the aid of a good illuminating apparatus, head mirror, tongue depressor, laryngoscope, etc., special attention being paid to certain irregular spaces most apt to harbor foreign bodies, viz., those about the anterior and posterior pillars of the fauces, the follicles of the tonsils, the lingual fossæ, the pyriform sinuses, the orifice of the œsophagus, and the interior of the larynx and trachea as far as its bifurcation. If it is lodged in the length of the œsophagus or bronchi, it will not be discovered by the above means; but other localities being excluded, it is an easy matter to determine from the obvious symptoms alone in which of these it is. If in the larynx or trachea, the symptoms nearly always present are slight pain and soreness at the point of location, a tickling sensation, and a sharp spasmodic violent cough, occurring irregularly with intervals of complete repose. The voice may or may not be affected at first, but nearly always is so later from the extension of the inflammatory reaction; for a foreign body long retained will usually set up inflammation in the tissues about it; isolated instances being recorded, however, of such bodies being retained for years and then being expelled, no symptoms developing to cause the patient uneasiness.

In cases of impaction in the lower pharynx or œsophagus immediate death may ensue from asphyxia caused by pressure on the larynx or trachea, or by reflex spasm of the glottis, there are apt to be coughing and dyspnœa in every case, especially if the body is high up in the gullet, and swallowing is difficult or impossible.

Having located the foreign body in the fauces, pharynx, or orifice of the œsophagus, it is usually a simple matter to remove it. In older persons, this can be done with a suitable pair of forceps, using cocaine, if necessary, to secure greater toleration; in small children the best work can be done under an anæsthetic, with the finger, which serves at once to discover the foreign body and to dislodge it. If it is lower down in the œsophagus proper, its passage onward to the stomach can often be hastened by taking a few swallows of water or other substance; or it may be ejected by causing the patient to vomit, and this is best done by tickling the fauces with a feather, or even the finger.

Should these proceedings fail or be deemed inexpedient owing to the nature of the foreign body, the horse-hair probang is often invaluable, serving either to extract or force it onward. All else failing, œsophagotomy is in order.

If the body is in the larynx or trachea and the symptoms are urgent, the operation should be performed at once—laryngotomy or low tracheotomy; if not, one must wait and try to effect its expulsion through the natural passages, as can sometimes be done with the patient in the supine and partly inverted position, by a deep inspiration followed by a forcible expiration, accompanied by sharp blows on the back or chest; or one may use cocaine and remove the body with the forceps, guided by the laryngoscope or finger. During these simpler manœuvres the constant danger of asphyxiation from reflex spasm of the glottis must ever be borne in mind.

It is very important that the foreign body be removed as soon as possible, for, while it remains, the patient's life is always in danger. However, if there is a doubt as to the diagnosis, which implies of course that the symptoms are very slight, the expectant plan of treatment may be tried, awaiting developments; otherwise, it is best to open the trachea at once, and if the foreign body is not immediately expelled by the vigorous coughing which follows the introduction of a free supply of cold air into the trachea, resort is again to be had to inversion; or if the foreign body is too firmly fixed to be moved by this method, probes or forceps are to be employed to loosen and extract it. If this is not possible, the foreign body can sometimes be forced upward into the mouth and then expelled. All methods failing, especially if there be much swelling

[1] Read before the Austin Flint Medical Club, March, 1899.

and consequent impaction, the wound in the trachea is to be kept open, either by sewing the edge of the mucous membrane and cartilages to the skin, or by bent wire retractors tied back of the neck with tapes. A piece of gauze should be fixed over the opening, and the atmosphere of the room kept warm and moist, awaiting the spontaneous loosening of the foreign body, when a repetition of former efforts will likely prove successful. If not, after a reasonable interval, the wound may be allowed to heal, no harm having been done.

## Clinical Department.

### A CASE OF ACROMEGALY.[1]

By A. HYMANSON, M.D.,

ATTENDING PHYSICIAN TO THE UNIVERSITY COLLEGE DISPENSARY, AND PHYSICIAN TO THE OLD MARION STREET MATERNITY HOSPITAL, OUT-DOOR DEPARTMENT.

Mrs. K. C——, thirty-nine years of age, was born in Russian Poland. She was married at the age of nineteen years, and menstruated first at the age of twenty-one, two years after her marriage. Her youngest child is five and one-half years old. Four children are living, and one died in infancy. She has always led a regular life and has never had any illness that she can remember. Her family history is good, there being no hereditary complaint and no specific trouble. Her parents died at the age of fifty-eight and always enjoyed good health. She has two younger sisters and one brother in perfect health. No one in her family has ever been afflicted as she is.

The beginning of the sickness was so gradual and insidious that neither she nor her relations can state accurately as to when the trouble set in, but she claims that she began to suffer intense pains in the head, eyes, and extremities about five years ago or more. The headache was continuous and most marked in the frontal and occipital regions. The pains in the back and extremities were intermittent. Her hands, feet, and face began to swell gradually, and her attention was particularly drawn at first to the disfigurement of the hands and face. The swelling of the extremities was accompanied by lancinating pains suggestive of rheumatism. She was suffering from cardiac palpitation, general debility, anorexia, and constipation, and had been taking medicine off and on without the slightest relief. Her present condition is as follows: The head is large; the face is elongated, oval in form, measuring from the frontal hair to the symphysis menti seven and one-half inches; the forehead is depressed and the superciliary ridges are prominent. The nose is much increased in size, in length as well as in width; it measures three inches in length and has an œdematous appearance. There is some exophthalmia; the eyelids are thickened, but can be moved readily in all directions, and the pupils react to light. There is some œdema under the eyelids. The ears are hypertrophied. The lower jaw takes part in the general enlargement of the bones of the face, and measures from condyle to condyle fifteen inches. The alveolar processes are widened; the tongue is thickened, broad and flat, and the lips are somewhat hypertrophied. The skin of the face is coarse, and exhibits a tendency to perspire. Articulation is slow, clumsy, and thick. The neck is greatly enlarged, measuring fourteen and one-half inches. The thyroid body is not enlarged. There is no evidence of enlarged thymus, and no dulness can be detected at the manubrium sterni. The scapulæ and the bones of the shoulder are somewhat enlarged; the sternum is broad. The ribs are prominent and thickened; the breasts are atrophied, the spine is bowed, and the heart and lungs are normal.

The abdomen is pendulous, and measures thirty-nine inches. The splenic dulness is normal. The pelvic bones are somewhat enlarged. The uterus is greatly hypertrophied, and there is an enormous prolapse of the genital organs. A few months ago she suffered from menorrhagia. The hands are greatly enlarged, mostly in breadth and thickness, and have a spade-like appearance, while the fingers and nails are broad. The thenar and hypothenar eminences take part in the general enlargement. The wrist and forearm are thickened. The circumference at the wrist is eight and one-half inches, and at the middle third of the forearm ten and one-half inches. The enlargement of the feet is not very marked, as the patient wears only one size larger shoe than she did some time ago. The lower extremities are œdematous, pit on pressure, and are tender to the touch. The skin, though coarse, is not thickened, dry, and harsh as in myxœdema. The patellar reflexes are delayed. The cutaneous sensibility is normal. The gait is clumsy. The senses of sight, smell, and hearing are not disturbed. She has mental dulness, answering questions rationally, but with some hesitation. The memory is defective. She has severe headaches, a sense of fatigue, and tinnitus aurium. She complains of severe rheumatic and neuralgic pains all over the body and extremities. Sweats are frequent on the slightest exertion. She complains of shortness of breath, cardiac palpitation, and occasionally has an asthmatic attack.

Examination of the urine does not show anything abnormal. The temperature is normal, and the pulse varies between 80 and 108 per minute. Of late, the patient has complained of paresis of the hands, and the fingers seem to her to be benumbed, but she moves them freely. She is always peevish, excitable, and irritable.

The patient was under my treatment for more than two years. I kept her on tonics, syrup of the hypophosphites, iron, arsenic, and the iodides, but without the slightest improvement: bromides, codeine, and antipyrin gave her some temporary relief for a few months. The nervous excitability rapidly subsided, the headache disappeared, and the patient slept well, but later on she became so accustomed to these drugs that even large doses did not affect her. From the 12th of March to the middle of September, 1897, a period of about six months, I fed her, by suggestion of Dr E. D. Fisher, on thyroid extract, one half a grain three times a day. One-half a grain of this extract represents five grains of the fresh gland.

After being under this treatment for two weeks, there was a striking improvement in her nervous condition, but later on I had to diminish the dose from time to time, because she occasionally showed symptoms of intoxication, due to the gland itself, a condition known as thyroidism. She had a very frequent pulse of 125 per minute, had fainting-spells, and a peculiar weakness of the lower extremities, paresis, and some alteration in her mental condition. She despised her family, and considered her husband as her enemy. For the last four months I administered to her extract of pituitary body, gr. i. three times a day, but without any improvement whatsoever.

Comparing the careful measurements I made two years ago of the hands, lower jaw, and feet, and those I have taken recently, it seems that all the medications we have at our command, even the modern ones, the animal extracts, have very little influence on this strange malady; in fact, my patient is much worse than before. Her rings which she wore two years ago are much too small for her, and her clothes are too tight. The circumference of her wrist two years ago was six inches, now it is eight and one-half; circum-

[1] Case presented before the Eastern Medical Society of the City of New York, January 14, 1898.

ference at the knuckles two years ago was nine and one-half inches, at present it is eleven and one-half, etc. Recently her face has changed much, a photograph which was taken more than a year ago does not show much deformity, but at present the head is much elongated, the lower maxillary bone is increased in size, the chin is projecting forward, and there is marked prognathism. Her friends can hardly recognize her; they say she had years ago a nice round face, now she is entirely disfigured. Her subjective symptoms are also going from bad to worse.

An *x*-ray photograph taken of her hands four months ago shows that the great increase in the size of the hands was due to over-growth of the soft tissues also, and not only to an alteration in the bones themselves. It is probable that we have to deal here with a case of acromegaly and some myxœdema combined, or there was some nutritional disturbance in the pituitary gland, and perhaps at the same time some sclerotic changes of the thyroid gland as well.

In view of the fact that in almost all cases of acromegaly the soft parts increase in size, and in some cases there are changes in the thyroid and thymus glands, and from the striking resemblance of the symptomatology of acromegaly and myxœdema, it is probable that many patients who were supposed to be purely acromegalic are suffering at the same time from myxœdema. Sir W. H Broadbent (*Lancet*, March 28, 1896) has described a patient with acromegaly under his care, in St. Mary's Hospital, the skiagraphs of whose hands and feet showed that the great increase in bulk was due to an overgrowth in the soft tissues only, and not to an alteration in the bones It is highly probable that some cases which did not show any appreciable result by the treatment of either pituitary or thyroid extract alone, but rapidly improved under a treatment of both extracts combined, were really cases in which some changes had taken place in both the pituitary body and thyroid gland.

## A UNIQUE CASE OF PITYRIASIS VERSICOLOR.

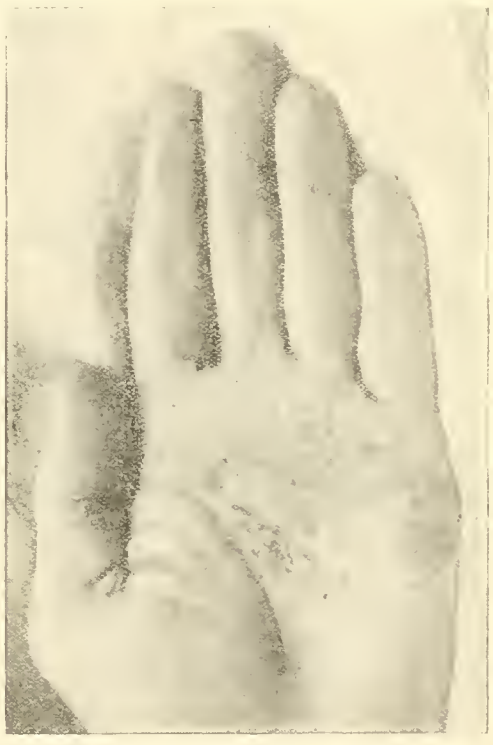
BY WILLIAM S GOTTHEIL, M D

NEW YORK

THE location and distribution of dermal efflorescences are important elements in the diagnosis of the diseases of which they are manifestations. An unusual localization therefore attracts attention, and a unique one, the very possibility of which is denied in the standard text-books, is worthy of record

Pityriasis versicolor, tinea versicolor, or chromophytosis, is said never to occur on the hands or feet, certainly never upon the palms or soles, even the possibility of its appearance on the extremities below the elbows and knees is denied I shall mention only a few authorities. Weyl and Geber, in Ziemssen's work, say that the comparatively rare occurrence of pityriasis versicolor on the neck and face is probably due to the fact that these parts are most frequently and thoroughly cleansed of the superficial epidermis in which the parasite proliferates It has never yet been observed, they say, upon the palms and soles, for the same reason Hyde says that it is rarely seen upon the lower extremities, still more rarely upon the face, and never on the hands and feet. It tends to avoid surfaces exposed to the light. Lesser says that it is extremely rare upon the face, and has never been found on the hands. Kaposi, Crocker, Wolff, Duhring, Robinson, and all the others agree that the malady is confined to the trunk and never occurs on the hands and feet. That this is not the fact, the following case will show

Dr. de V——, a Cuban physician, consulted me, on October 22d of last year, for some black spots which had been present upon his left palm for fifteen years. A single one had appeared first, and had spread very slowly, and similar new ones had appeared from time to time in its vicinity, and enlarged gradually. For some years past it had been stationary. It looked bad, but caused him no discomfort or subjective sensations. He had used various applications, without much effect. Dr. de V—— was of opinion that the affection was parasitic, for on several occasions he had removed it apparently entirely by scraping the skin with a knife-blade, but it had always returned quickly within twenty-four hours. Examination showed that the centre of the left palm was occupied by the efflorescence, which extended well on to the inner border of the hand. The fingers, wrists, and dorsum were free; and I may mention here at once



that there was no trace of the eruption upon any other part of the body The eruption itself consisted of discrete rounded macules, fusing in a few places into larger patches. The color of the efflorescence was a dark brownish black. There was slight scaling, and with a penknife the superficial scales could be removed, carrying with them the entire eruption, and leaving an apparently normal, uncolored epidermis behind Examination of these scales under the microscope immediately revealed the nature of the eruption. The epithelium cells were comparatively few, the entire field being covered with mycelium and spores. The former was in threads of about 0.005 mm. diameter, generally short, and rarely branching. The spores were mostly in heaps, and consisted of highly refracting circular and oval bodies a little larger in diameter The entire microscopic appearance of the fungus was characteristic, the microsporon furfur, the cause of pityriasis versicolor, being in appearance the most definite and readily recognized of the dermatophyta.

The color of the eruption was peculiar, I have never seen it so dark, so nearly approaching black. The hue does vary, however, within wide limits in pityriasis versicolor It may be reddish, yellowish, or brownish, for the microsporon takes up extraneous coloring matter with ease, and can be readily stained

with many of our ordinary reagents. I have in my possession a water-color sketch of a case in which the eruption was a vivid brick-red in color, due undoubtedly to staining with the coloring matter carried by the abundant sweat from a new red flannel undershirt that the patient wore. The coloring matter in this present case was probably atmospheric dust, and matter derived from the clothing and other articles with which the hand came in contact.

It is evident, therefore, that in rare instances the microsporon furfur will grow on parts exposed to the light, and that ordinary ablutions, and even the specially thorough ones that a medical practitioner of necessity performs, are not sufficient in all cases to prevent the development of the fungus.

144 West Forty-eighth Street.

## Progress of Medical Science.

**Some Therapeutic Applications of Cold.** — Ewart (*Lancet*, April 8, 1899, p. 955) relates two cases of rheumatoid arthritis and one of pemphigus with acute and painful joint lesions in which, other measures failing, relief was afforded by massage of the affected parts with blocks of ice. Encouraging results were obtained also in the relief of the severe pleuritic pain accompanying acute pneumonia of the base.

**Alcoholism Simulating Meningitis in Children.**—Drs. Ausset and Combernale report (Société de Médecine du Nord, February 24th) two cases of this affection, one in a nursling, the other in an infant two and one-half years old, simulating meningitis. In both cases alcoholism was recognized as the cause; in the first case produced by the milk of an alcohol imbibing wetnurse, in the other by the direct administration of alcoholics to the infant. In both cases the symptoms disappeared upon the removal of the cause.

**Gastric Crises.**—Dr. Seymour Basch (*Archiv fur Verdauungs-Krankheiten*, Bd. v., 1899) says, that naturally in the early stages of locomotor ataxia, when the gastric crisis forms the only symptom of the disease, the diagnosis cannot be made with positiveness. In addition to this, the presence of at least two characteristic symptoms is necessary. Still, the typical gastric crises of tabes are also valuable for the diagnosis of this disease, since they are characterized by the following points. (1) Entire absence of all symptoms of any organic disease of the gastro intestinal tract. (2) Suddenness of the onset of the attacks. (3) Absence of initial chill. (4) Great intensity of the symptoms, which sometimes increase rapidly at other times gradually, in severity. (5) Absence of fever, rapid pulse. (6) Absence of any local condition in the gastric region or of other factors which could explain the severity of the existing symptoms. (7) Absence of characteristic qualities in the vomit. (8) Absence of every influence upon the course of the affection by external circumstances. (9) Spontaneous abatement of the attacks. (10) Speedy convalescence.

**The Transplantation of Nerves.**—Dr. Reuben Peterson (*American Journal of the Medical Sciences*, April) concludes as follows: (1) Transplantation of a peripheral nerve segment to bridge over a gap between the two ends of a resected nerve is a legitimate surgical procedure. (2) Under favorable conditions at least partial, and at times complete, restoration of sensation and motion may be expected to follow the operation. (3) Regeneration of the degenerated peripheral end is due to down-growths from the axis-cylinders of the central end. (4) Because of the slowness of the process the longer the time after operation the more favorable will be the results. (5) Sensation may return very early after operation, and, as a rule, precedes return of motion. (6) This rapid return of sensation is not due to down-growth of axis-cylinders or to conductivity of the transplanted fragment, but must be explained by collateral nerve supply. (7) In many cases very early return of motion after transplantation may be due to vicarious movements of other muscles than those formerly paralyzed, and not to a regeneration of the latter's nerve supply.

**Cerebral Tumor: Differential Diagnosis.**—E. S. Reynolds (*British Medical Journal*, February 11th) divides the subject as follows:

(A) Brain tumor may be simulated by: (1) Chlorosis. Very rarely optic neuritis, generally of rapid onset, is present. If it is associated with headache and hysterical motor or sensory symptoms, a mistake is easily made. (2) Uræmia, with intense headache, optic neuritis, convulsions, and coma, especially if the convulsions are unilateral. The character of the optic neuritis and the history and symptoms of Bright's disease should make the diagnosis clear. (3) Chronic plumbism, with encephalopathy, convulsions, delirium, acute mania, coma, optic neuritis, and headache, esecially if there is hemianæsthesia and paralysis of cranial nerves. Buzzard has described paralysis of the third nerve, and the writer has seen paralysis of both sixth nerves. (4) Hysteria when there are headache, vomiting, and strabismus. (5) So called reflex epilepsy. (6) Syphilis of the cranial nerves with headache. (7) Meningitis, or brain abscess. (8) Polioencephalitis may simulate pontine tumor.

(B) Brain tumor may simulate other diseases: (1) Hysteria if there are no optic neuritis and no paralysis of nerves. (2) Reflex epilepsy may be assigned as the cause of unilateral convulsions if there has been an injury to or if there is a tumor on a nerve. (3) Hydrophobia, if there is history of a dog-bite. (4) Senile dementia. (5) Circulatory changes, if the symptoms are of sudden onset.

**Chronic Appendicitis and Movable Kidney.**—G. M. Edebohls (*Post-Graduate*, February) concludes as follows: Chronic appendicitis is present in from eighty to ninety per cent. of women with a symptom producing movable right kidney. This frequency constitutes chronic appendicitis one of the chief, if not the chief, symptom of movable kidney. Chronic appendicitis, by reason of its frequency, the protracted suffering, and serious impairment of health which it entails, and the dangerous possibilities of implanted acute attacks of appendicitis, may be considered the most important complication of movable right kidney. The writer's statistics show that twenty per cent. of all women have movable kidney or kidneys, that four per cent. of all women have symptom producing movable kidneys or kidneys; that four per cent. of all women have appendicitis, that while three-and one-half per cent. of all women have both symptom producing movable kidney and appendicitis, only one-half of all women have appendicitis and well anchored kidneys. The startling nature and importance of the conclusions to be drawn from these statistics do not invalidate the latter. Satisfactory investigation of the relations of movable kidney and appendicitis became possible only after the discovery and elaboration of the writer's method of palpation of the vermiform appendix. It remains impossible to those not practically familiar with the method. Chronic appendicitis may be the only symptom of movable right kidney. Some of the symptoms commonly ascribed to movable kidney are often in reality due to the concomitant appendicitis.

MEDICAL RECORD:

## NEOPLASM OF THE LEFT THIRD FRONTAL CONVOLUTION IN A RIGHT-HANDED INDIVIDUAL, WITHOUT APHASIA.

EXPERIENCE is constantly teaching the medical man to be surprised at nothing and always to be prepared for the unexpected. Didactically we recognize types of disease, but clinically we encounter the greatest diversity of symptom-groupings. In connection with no condition perhaps is this statement better illustrated than with tumor of the brain. It is not an uncommon experience for such a lesion to be diagnosticated during life and not be found after death, and *vice versa*, and even when the presence of a growth has been recognized, its situation and histological constitution may baffle the highest diagnostic skill and acumen. A slowly growing tumor may give rise to few or no symptoms, while a large neoplasm may, by reason of the physical conditions present within the cranium, occasion symptoms by disturbance of the function of parts remote from the seat of actual disease. Further, there may be aberrations not only in structure but also in function. For instance, the motor tracts may in large part fail in their usual decussation, then it is surmised that certain parts of the brain acquire special functions in accordance with the uses to which the peripheral organs they govern are put. Thus it is agreed that the nervous motor mechanism controlling speech is located in the left third frontal convolution in right-handed persons, although it is believed to have also a latent or undeveloped representation on the right side of the brain. In the same way the mind-auditory centre is located in the left first temporal convolution, and the mind-visual centre in or about the angular gyrus.

Of the uncertainty of diagnosis of brain tumor and of cerebral localization additional evidence is afforded by the report by Collier (*The Lancet*, March 25, 1899) of a case in which complete destruction of the third frontal convolution on the left side of the brain by a neoplasm in a right-handed person was unattended with aphasia. The patient was an unmarried woman, twenty-three years old, whose mother had died from carcinoma, and who, a year and a half before death, while walking with her sister, suddenly, and without warning, fell and became unconscious for a few minutes. The face was pale, but there was no convulsion or biting of the tongue or involuntary passage of urine. In the following fortnight two attacks of similar character took place, although in the second the teeth were clenched, and slight convulsive movements, with foaming at the mouth, occurred. Subsequently there were frequent sudden attacks of giddiness, pallor, and faintness, which were not followed by any noticeable speech defect. Examination at this time failed to disclose evidence of organic disease, and under treatment with bromides the attacks of giddiness became much less frequent.

After some seventeen months the patient was thought to be a little dull mentally, and she complained sometimes of slight headache. On one occasion she was noticed to mumble in her speech and to use wrong words for a period of half an hour. A little later she became heavy and somnolent and finally comatose. Ophthalmoscopic examination now revealed recent optic neuritis. There were also complete palsy of the right sixth nerve and almost complete palsy of the left sixth nerve; and the lower portion of the left side of the face did not move quite so well as the right. There was neither hemianopsia nor word-blindness. The patient was right-handed, and there was no history of left-handedness in the family. Motility and sensibility in the trunk and limbs were natural. There was no headache or tenderness. The knee jerks were not exaggerated, although the left was rather the more readily elicited. The wrist-jerks and the elbow jerks were active and equal. The plantar reflexes exhibited a flexor response on either side. The stupor gradually deepened, the breathing became stertorous, the temperature ranged between 100° and 102° F., and death resulted from respiratory failure.

Upon post-mortem examination the dura was found adherent to the anterior part of the left temporo-sphenoidal lobe over a small area. The pia-arachnoid at the base exhibited considerable old patchy thickening. There was slight recent meningitis over the posterior extremities of the second and third left frontal convolutions and over the anterior part of the left temporo-sphenoidal lobe. The cortex of the posterior end of the third frontal convolution, including that part between the ascending and posterior limbs of the Sylvian fissure and the contiguous part of the left temporo-sphenoidal lobe, presented a gray, jelly-like aspect, suggesting the presence of a glioma. On the inferior aspect of the brain was a growth, arising from the posterior part of the orbital lobule and filling the left Sylvian fissure.

After the brain was hardened in formalin the neoplasm was found to involve the inferior margin of the left second frontal convolution at about its middle, the whole posterior part of the left third frontal convolution, the posterior part of the orbital lobule, and to a small extent the anterior gyrus of the island of Reil. For some distance around the growth the white matter of the centrum ovale was softer than elsewhere. The ascending frontal convolution was uninvolved and the whole of the right hemisphere appeared healthy. On microscopic examination the growth was found to consist of small round-celled tissue, the cells being densely aggregated around the blood-vessels, which were greatly thickened.

This case shows among other things that the nervous motor mechanism governing the function of speech may be primarily developed in the right hemisphere, even in right-handed persons. Such development takes place in varying degree after aphasia due to destructive lesions of the left third frontal convolution, but there was no evidence, clinical or pathological, congenital or acquired, in the case reported of such structural disturbance.

## DE LUNATICO INQUIRENDO.

Mr. Purrington, of the New York bar, has recently put himself to the trouble of trying to get something rational out of the unchristian and unscientific "Christian Scientists." He has recently, in a communication to *The Sun*, given us part of the correspondence between himself and a person named Norton, as to what the latter would do in certain surgical contingencies which are mentioned. The questioner showed remarkable forbearance and pertinacity, but was utterly unable to get a straightforward answer. He put a perfectly plain question to Norton on the subject of stopping arterial hemorrhage by "mental" therapeutics, with inferentially the repair of the artery, but could get no answer in spite of a specific promise, although Norton was quite ready to declare that it was certainly possible to stop such bleeding and to relieve several other surgical conditions by what he was pleased to call mental therapeutics. He would not tell how it was done, however. He tried to obscure the subject with verbiage, among other collections of words emitting the following: "I make no diagnosis except along the lines of consistent mental therapeutics. An expert in mental therapeutics will naturally know the character of this diagnosis. Discord is discord. Pain is pain. Disease is disease," etc. Instead of answering a series of questions submitted to him, the poor man delivers himself thus: "I have but to repeat—that I prefer to shelve them, because to answer them would bring about wholly indifferent results." Ordinarily rational individuals have in many cases a hesitation about curbing these people for fear that there should seem to be any interference with religious liberty. However, there is a sharp line between religious liberty and license to commit felony in the name of religion. One of this same brand of "healer" was convicted in Brooklyn recently, and the result may be salutary, but it would probably be beter if one of the leading lights could be caught red-handed and sent to prison or an asylum. They certainly are suffering from systematized delusions in many cases, and the logical outcome of their reasoning is too frequently homicide. If these people did not commit acts so demonstrably contrary to knowledge, experience, and scientific experiment, we should perhaps not be justified in active interference. But they have committed such acts repeatedly, and there ought to be a legal hold upon them without waiting for the immolation of more foolish or helpless victims. A commission in lunacy might be desirable in some cases.

## THE SMOKE NUISANCE IN LONDON.

American cities have their troubles. In New York, the street noises are distracting, the paving of many of the principal thoroughfares leaves much to be desired, the cleaning of the streets generally is conducted on a system by no means perfect, buildings are in a large number of instances too lofty, and lastly the elevated railway is hardly a thing of beauty. In Philadelphia the water supply is lacking in most of those features that tend to conduce to the well-being of the community at large. Chicago—despite the fact that its inhabitants proudly proclaim it the ideal city of the universe—according to the views of unprejudiced sanitarians, does not quite reach this high position. And thus with all the large centres of population faults may be descried in their matters hygienic.

Now London—with the possible exception of street noises, which, however, at their worst do not possess the peculiarly excruciating, nerve-disturbing qualities of those of New York—is in respect of paving and sanitary arrangements generally perhaps in advance of many American cities. But unfortunately London has one drawback of so serious a character as almost to outweigh all its advantages. It need scarcely be said that the oft-recurring fog is referred to. Staunch and patriotic cockneys will stoutly aver that the murky atmosphere of the British metropolis is healthy, exhilarating, and refreshing. Nevertheless, with this view of the situation medical men are not in accord. On the contrary, it is claimed by those concerned with the question of public hygiene that the dirt-laden air of London is a fruitful means of ill-health and death. Statistics show that London enjoys just about half the sunshine of British inland towns, and one-third of those on the south coast of the island.

Many theories have been put forward to account for the prevalence of London fogs, but it is now agreed on all hands that the use of soft coal is the principal cause of the evil. It is pointed out that in cities where wood or anthracite coal is consumed fogs are comparatively rare. From an æsthetic and artistic as well as from a sanitary standpoint this condition of affairs is lamentable. The very buildings themselves take on a gloomy, dusky, funereal aspect, and architecture suffers in an equal degree. A change, however, is in sight, for the Smoke Abatement Society has come to the rescue. While many are fighting Sir William Richmond, the artist, on the question of his decorations in St. Paul's Cathedral, Sir William is himself pursuing a campaign against the smoke of London. He is the president of the Smoke Abatement Society, which is attracting leaders of the artistic and scientific circles of the metropolis. The remedy suggested is that the consumption of bituminous coal should be restricted or wholly prohibited, and it is contended that if this were done the atmosphere of London would be as pure and clear as that of any other town. The crusade has our good wishes, and we trust it will not end in smoke, but rather put an end to it. New York is not so free from the soft-coal nuisance that we can view with indifference efforts to abate it elsewhere.

## News of the Week.

**Mount Sinai Hospital.** — Dr. Joseph Wiener, Jr., has been appointed adjunct attending surgeon to the Mount Sinai Hospital.

**Prof. A. Jacobi, M.D.**—Foreign membership was conferred on Dr. A. Jacobi, of this city, by the "Société d'Obstétrique, de Gynécologie, et de Pédiatrie" of Paris, on June 2d.

**A Fair in Aid of the Charing Cross Hospital.**—The receipts of the bazaar in aid of the Charing Cross Hospital, London, which was opened by the Princess Louise on Wednesday of last week, were £13,300.

**Burning of a Leper Lazaretto.**—News was received recently at Victoria, B. C., of the destruction of the D'Arcy Island leper station by fire. One leper was killed, and another, it is feared, will die from injuries received.

**The Chicago Medical Society.**—At the annual meeting of this society, held June 21st, the following officers were elected: *President*, Dr. Junius C. Hoag; *Vice-Presidents*, Drs. Henry B. Favill and Hugh T. Patrick; *Secretary*, Dr. Arthur R. Edwards; *Treasurer*, Dr. S. C. Plummer, Jr.; *Trustees*, Drs. John M. Dodson, A. D. Bevan, and Sanger Brown.

**The Tri-State Medical Association of Maryland, West Virginia, and Western Pennsylvania,** in session recently at Markleton Sanitarium, Pa., elected the following officers: *President*, Dr. J. M. Spear, Cumberland, Md.; *Vice-Presidents*, Drs. Americus Enfield, Bedford, Pa., Robert Gerstelle, Elk Garden, W. Va., and W. J. Craigen, Cumberland, Md.; *Recording Secretary*, Dr. Percival W. Lantz, Alaska, W. Va.; *Corresponding Secretary*, Dr. F. W. Fochtman, Cumberland, Md.; *Treasurer*, Dr. H. W. Hodgson, Cumberland, Md.

**The New York County Medico-Pharmaceutical League** was incorporated recently at Albany. The objects of the league are stated to be to encourage operations at the patient's home, where practicable; to regulate lodge-contracting, dispensaries, hospitals, and other medical charities, and to discuss and regulate other matters of mutual interest to the medical and pharmaceutical professions. The directors for the first year are Samuel F. Brothers, Ph.G., M.D., Julius Kalish, Lazarus W. Zwisohn, Victor Lowenberg, Maurice Fishberg, M.D., Louis Lurie, Ph.G., Hirsch Beck, M.D., Lazarus Dillon, Henry Goldberg, M.D., and Samuel Epstein.

**New York State Medical Examinations.**—The following were the results of the medical licensing examinations held in this State in May: Total number of candidates, 131; successful number of candidates, 111; rejected, 20; percentage of rejections, 15.27; percentage successful, 84.73; total number of honor candidates, 10; highest general average, 95.3 per cent.; rejections in anatomy, 12; rejections in chemistry, 7; rejections in surgery, 3; rejections in pathology and diagnosis, 9; rejections in physiology and hygiene, 3; rejections in obstetrics, 3; rejections in therapeutics, practice, and materia medica, 9. Rejections in one topic, 10, rejections in two topics, 3; rejections in three topics, 1; rejections in four topics, 3; rejections in five topics, 3; rejections in six and rejections in seven, none.

**Trial of Yellow-Fever Antitoxin.**—Health Officer A. H. Doty has perfected arrangements with Dr. Eduardo Licéaga, of the Mexican national board of health, to use the yellow-fever serum, described in another column by Dr. Fitzgerald, in Vera Cruz, where there is now an epidemic of the disease.

**Yellow Fever at Santiago.**—Two new cases of yellow fever and four deaths from the disease were officially reported in Santiago on June 26th. This makes a total since the outbreak of the disease of thirty-five cases and eleven deaths. The army surgeons now think they have the fever under control.

**Removal of the Blind Asylum.**—The managers of the New York Institution for the Blind, in Ninth Avenue, between Thirty-third and Thirty-fourth streets, have decided to remove the seat of the institution from its present ground to a tract of thirty acres between One Hundred and Sixty-fifth Street, One Hundred and Sixty-eighth Street, Eleventh Avenue and the Hudson River.

**For a Department of Public Health.**—At the recent meeting of the American Institute of Homœopathy Dr. M. O. Terry, of Utica, ex-surgeon-general of the National Guard of New York, offered a resolution to the effect that in the opinion of the society the condition of the country and its standing among the progressive nations of the world demand for its medical department a position in the cabinet equal in all respects to the other departments of the government.

**The International Congress of Women** was opened in London on Monday of this week. The Countess of Aberdeen, the president of the International Council, delivered a speech of welcome to the delegates, in the course of which she gave a history of the women's movement for the past fifty years, which, she said, had produced a revolution in the position, responsibilities, and opportunities of women.

**Italian Society of Laryngology, Otology, and Rhinology.**—The fourth annual meeting of this society will be held in Rome, in October, under the presidency of Dr. Guiseppe Gradenigo, of Turin. The subjects for set discussion are: "The Channels and Modes of Diffusion of Tympano-Mastoidean Infection," opened by Dr. Camillo Poli, of Genoa; "The Physio-Pathology of the Olfactory Nerves," opened by Dr. Vittorio Grazzi, of Pisa; and "The Parasyphilitic or Postsyphilitic Lesions of the Larynx," by Dr. A. Trifiletti, of Naples. The question of the proper designation of a specialist in oto-rhino-laryngology will also be discussed.

**The American Surgical Association.**—At the recent meeting of this association in Chicago, the following officers were elected for the ensuing year:

*President*, Dr. Robert F. Weir, New York City; *First Vice-President*, Dr. Charles B. Nancrede, Ann Arbor, Mich.; *Second Vice-President*, Dr. Edmond Souchon, New Orleans, La.; *Secretary*, Dr. Herbert L. Burrell, Boston; *Treasurer*, Dr. George R. Fowler, Brooklyn, N. Y.; *Recorder*, Dr. De Forest Willard, Philadelphia; *Member of the Council*, Dr. W. W. Keen, Philadelphia.

**The Army Board on the Spread of Typhoid Fever.**—Forecasts of the report of the board appointed by the War Department to study the distribution of typhoid fever in army camps, to be made about the end of July, indicate that the water supply had practically little to do with the spread of the disease. The infection, the report will say, was transmitted through the atmosphere in dust carried by the wind and by the agency of flies.

**The Study of Practical Philanthropy.**—A class in philanthropic work has been organized by officers of the Charity Organization Society of New York. Among the pupils are agents of several of the State boards of charities, who wish to familiarize themselves with the methods for the relief of the poor. The students come from Harvard, Yale, and Columbia Universities, the University of Chicago, from Denver, and from San Francisco. They listen to lectures, visit institutions, and do office work for the Charity Organization Society.

**A New Homœopathic Society.**—During the recent session of the American Institute of Homœopathy at Atlantic City a new surgical society was organized which will be known as the Surgical and Gynæcological Association of the American Institute of Homœopathy. Dr. W. B. Van Lennep, of Philadelphia, was elected *President*; Dr. George W. Roberts, of New York, *Secretary*, and Dr. Hartman, of Syracuse, *Treasurer*. The association will meet annually at the same time and place as the institute.

**A New Disease among Miners.**—Drs. Rogers, Brodie, and Hamilton, of Johannesburg, have lately published the results of some researches upon what they consider a new disease prevalent among mine Kafirs in the Golden City, and very fatal. They call it "acute specific rhinitis," and consider it due to a diplococcus, which they think is identical with Fraenkel's pneumococcus, only more virulent. The morbid appearances, as shown in twenty-six cases, are a purulent rhinitis leading to meningitis, suppuration of the sinuses, middle-ear suppuration, and parotitis. Croupous pneumonia was present in most of the cases, and there was generally peritoneal effusion. The cases with no pneumonia or very little were as fatal as the others. Dysenteric diarrhœa generally occurred at the last.—*The Medical Press.*

**The Medical Society of North Carolina** held its forty-sixth annual meeting at Asheville on May 30th and June 1st and 2d. The election of officers resulted in the choice of the following: *President*, Dr. George W. Long, of Alamance; *Vice-Presidents*, Drs. Chalmers M. Poole, of Craven, John Hay Williams, of Asheville, J. M. Parrot, of Kinston, and W. D. Hilliard, of Asheville; *Secretary*, Dr. George W. Pressly, of Charlotte; *Treasurer*, Dr. G. T. Sikes, of Grisson. The next place of meeting will be Tarboro.

**The Chigger,** so well known and of such ill-repute in the West Indies and West Africa, has recently invaded East Africa. The Indian coolies working on the Uganda railroad have been found to be infected with the parasite, and the Indian authorities are now wondering how they can prevent its spread throughout India when these coolie laborers return to their homes.

**"Mens Conscia Recti"** is the motto which has been proposed for the newly organized Proctological Society. An English contemporary suggests that the members of this association of rectal specialists be called proctitioners in contradistinction to their *confrères* whose practice is not confined within such narrow limits.

**The Connecticut State Medical Society.**—At the one hundred and seventh annual meeting of this society, held in Hartford on May 24th, the following officers were elected: *President*, Dr. C. S. Rodman, of Waterbury; *Vice-President*, Dr. L. B. Almy, of Norwich; *Treasurer*, Dr. W. W. Knight, of Hartford; *Committee on Matters of Professional Interest in the State*, Drs. T. T. Simpson, of Putnam, J. G. Stanton, of New London, and L. W. Bacon, of New Haven.

**The Illinois State Medical Society.**—At the annual meeting of this society, held in Cairo, May 16th, 17th, and 18th, the following officers were elected: *President*, Dr. Harold N. Moyer, of Chicago; *Vice-President*, Dr. John T. McNally, of Carbondale; *Secretary*, Dr. E. W. Weir, of Ottawa; *Treasurer*, Dr. George N. Kreider, of Springfield. The next annual meeting, which will be the semi-centennial, will be held in Springfield.

**The Queen's Eyesight.**—Commenting upon the recent reports that Queen Victoria was about to undergo an operation at the hands of a German oculist for cataract, *The British Medical Journal* says: "We have the best authority for stating that the alarming paragraphs regarding the queen's eyesight which have appeared lately are erroneous and misleading. For a considerable time Her Majesty's eyesight has been to some extent impaired owing to changes incidental to advanced years, but we are glad to be in a position to say that the deterioration has ceased to be progressive, and that the queen's eyesight has in no respect become worse during the last few years. All reports to the contrary, as well as the rumor of any impending or even contemplated operation, are therefore pure inventions."

**The British Association for the Advancement of Science** will meet this year at Dover in September. The president will be Prof. Michael Foster, and the presidents of the various sections are as follows: mathematical and physical science, Prof. J. H. Poynting; chemistry, Mr. Horace T. Brown; geology, Sir Archibald Geikie; zoology, Mr. Adam Sedgwick; geography, Sir John Murray; economical science,

Mr. Henry Higgs; mechanical science, Sir William White, anthropology, Mr. C. H Read. physiology, Mr. J. N. Langley; botany, Sir George King.

The Hospital Ship "Relief" sailed from Manila on June 22d for San Francisco with two hundred and fifty invalided soldiers on board.

Orrhotherapy of Cancer.—It is reported that Drs. Roquette and Lebro, of the Belgian Royal Academy of Medicine, have perfected a serum for the cure of carcinoma. The claim for efficacy of the remedy is said to rest upon the results of experiments upon some twenty horses.

An Investigation of Christian Science.—At the June meeting of the Medico-Legal Society, held in this city a few days ago, the president was authorized to appoint a committee to investigate the methods of Christian Science healers and to determine as to the necessity of a law to put a stop to their practices.

Sunstrokes in New York.—For the week ending June 10th, with the temperature at 95 F. at its highest point and a mean of 78 F. night and day, there were eighty-five cases of death from sunstroke. In the corresponding period of last year there were then only three cases of death from the same cause. Through the month of June, 1896, there were thirty deaths from sunstroke. A mortality from sunstroke during the early part of June, such as the city lately experienced, is of rare occurrence.

The Proof of Immortality.—Professor Hyslop, of Columbia College, is said to have become convinced of a future life through the revelations of a medium, but an English contemporary announces a much more convincing demonstration. We read in *The Scalpel* for May, 1899, that the address on surgery at the approaching meeting of the British Medical Association will be delivered by Mr. Greig Smith. As the gentleman mentioned died in June, 1897, his appearance at this time as an orator before the assembled physicians of Great Britain and Ireland should be sufficient to convince the most materialistic of sceptics

Missouri State Medical Association.—At the annual meeting of this association, held at Sedalia May 16th and 17th, the following officers were elected to serve for the ensuing year *President*, Dr. W B. Dorsett, of St. Louis, *First Vice-President*, Dr B. F. Binnie, of Kansas City, *Second Vice-President*, Dr. G. M. Nichols, of Higbee, *Third Vice President*, Dr. C. W. Overstreet, of Sedalia, *Fourth Vice-President*, Dr. C. R. Day, of Mayview, *Fifth Vice-President*, Dr E. L. Priest, of Nevada: *Recording Secretary*, Dr. B. C. Hyde, of Kansas City, *Assistant Recording Secretary*, Dr. J. S. Myer, of St. Louis, *Corresponding Secretary*, Dr. E. S Cave, of Mexico; *Treasurer*, Dr. J. F. Welch, of Salisbury. The next meeting will be held in the town of Mexico, Mo.

The End of the Case against Dr. Cleaveland.—The case against Dr. Trumbull W. Cleaveland, who was arrested again some time ago after the failure of two indictments against him on the charge of causing the death of an infant in April, 1897, by prescribing for her excessive doses of salol and resorcin, was dismissed last week by Magistrate Wentworth. No two of the medical experts called as witnesses for the prosecution at the preliminary examination agreed as to the cause of the child's death. One said the death of the baby was caused by the salol and resorcin; another said he did not think it was; another said the cause of death was croupous pneumonia, and still another thought it was heart failure. After such a mass of conflicting testimony, Dr. Cleaveland's counsel did not put in any evidence for the defence, simply moving that his client be discharged. The magistrate granted the motion. Of course there could be no other termination to the case, and Dr. Cleaveland is to be congratulated upon the end of his persecution.

Dr. Frederick A. Cook, of Brooklyn, has returned from the Antarctic region, where he has been for over a year, having gone as surgeon and anthropologist to the Belgian Antarctic expedition.

Yellow Fever at Panama.—Over forty cases and twenty deaths from yellow fever were reported at Panama during the months of May and June. Colon, on this side of the isthmus, has remained entirely free from the disease.

American Physicians in Cuba.—A petition has been presented to General Brooke from a number of physicians in Havana, praying that Americans be not allowed to practise medicine in Cuba without passing a licensing examination.

The Plague on a Pacific Steamship.—The steamer *Nippon Maru*, which reached Honolulu on June 17th, was held in quarantine on the report that a death had occurred three days before of bubonic plague. The steamer was quarantined for a week at Nagasaki because of a suspicious death. A second death occurred three days before the vessel reached Honolulu. The ship surgeon displayed the yellow flag on arriving, and Drs. Day and Carmichael found, after an exhaustive examination, evidences of bubonic plague bacilli The body was cremated and the steamer ordered into quarantine for a week.

The Society for the Prevention of Cruelty to Children.—The supreme court of this State has decided that the State board of charities has the right to inspect and to assume a general supervision over the Society for the Prevention of Cruelty to Children. The lower courts some time ago decided that the board had the right to inspect the books, papers, grounds, and buildings of the Society for the Prevention of Cruelty to Children in so far as they appertained to the care of abused or neglected children. The society appealed against this decision, and has come out worse than before, for now it has been decided that the State board should have control over all the workings of the institution.

The Lapses of a Contemporary.—In the issues for June 10th and 17th of a Quaker City "medic journal, whose stone man was recently convicted of lifting items from our columns, is a report of the annual meeting of the American Surgical Association at Chicago. This was prepared by the official reporter of the

association and sent in duplicate to several of the weekly medical journals, but was asserted by our veracious contemporary to be "from our special correspondent." The same paper for June 17th contained four items, purporting to be original editorial articles, which were absolutely literal reproductions, without credit of course, of portions of a letter previously published under the head of "special correspondence" in the *Boston Medical and Surgical Journal*. Some time ago the now backslidden editor of this same immoral weekly confessed—we doubt not with all the sincerity at the time of a Salvation Army convert—"It is an appropriate time to quit lying in medical journalism."

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending June 24, 1899. June 16th.—Surgeon L. W. Atlee detached from the *Boston* and ordered to the *Bennington*. Passed Assistant Surgeon B. R. Ward detached from the *Bennington* and ordered to the *Boston*. Assistant Surgeon F. M. Furlong detached from the *Independence*, June 30th, and ordered to the *Solace* temporarily, for passage to the Asiatic station. June 20th.—Surgeon C. G. Herndon on completion of temporary duty at recruiting rendezvous at Chicago, Ill., Cleveland, Ohio, etc., ordered home to wait orders. June 22d.—Medical Inspector R. A. Marmion detached from the Washington navy yard, July 1st, and ordered home to wait orders. Surgeon S. H Dickson ordered to the Washington navy yard, July 1st.

**Gladstone's Bird Eye.**—An English journal of the icteric type recently published a notice of Mr. Gladstone, in which it mentioned, as a partial explanation of his power in debate, that he had nictitating membranes in each of his eyes, and that he could by winking them during argument so startle his opponent as to leave him speechless.

**Cancer and the Water Supply.**—Mr. Alfred Palmer, a civil engineer, writes as follows to the editor of *The Practitioner*. "Referring to your articles upon the 'Cancer Scourge' which have been so freely commented upon in the various newspapers, I happened to work on the survey of the proposed railway from Athens in Greece to the Turkish frontier, and while stationed at Thebes I understood from several Greek medical men educated at Paris that the city was practically free from cancer on account of its pure water supply, as well as the geological formation of the surrounding country, which I should say is largely 'silurian.' At any rate, it would not take very long for a few English medical experts to make an investigation."

**Isolation of Lepers in Cuba.**—The sanitary authorities of Havana have ordered the sequestration of all lepers in the city, and up to the end of April ten or twelve, some of them of well-to-do families, have been apprehended and confined in the San Lázaro Hospital. This hospital, we learn from the *Archives de la Policlinica*, as well as others in Santa Clara and Puerto Principe, are asylums for lepers who voluntarily seek their protection. But confinement there has not hitherto been obligatory, nor was the isolation complete, as the patients were always allowed to go out during certain hours without any restriction on their movements.

**The Late Dr. Henry E. Crampton.**—The following resolutions were adopted at a meeting of the Harlem Medical Association, held June 12th:

"The members of Harlem Medical Association, having heard with deep regret of the death of their late associate, Dr. Henry E. Crampton, desire hereby to express their appreciation of his upright, kindly, and cheerful character, and of the great loss which the profession has suffered in the untimely removal of one of its members, who was more than ordinarily prominent in many fields of usefulness to his fellowman outside of the purely professional round of duties.

"The association desires further to express the deepest sympathy with the near relatives of the doctor, upon whom the loss of husband and father falls most heavily, and who could appreciate the beauty and sweetness of his character.

"*Committee*, Richard Van Santvoord (*Chairman*), J. C. Joseph Bird, Joseph E. Lumbard."

**Obituary Notes.**—Dr. Walter M. Wright, of Orange, Mass., died on June 24th, at the age of fifty-three years. He was medical examiner for the Eastern District of Franklin County, and also a member of the board of Franklin County pension commissioners. He was an alternate to the St. Louis convention three years ago. He was graduated from Dartmouth Medical College in 1874, and had practised medicine in Orange for twenty years.—Dr. Ira De Witt Brown, of Weedsport, N. Y., died on June 23d, at the age of sixty-eight years. He was born in Vernon, N. Y., and was graduated from the Albany Medical College in 1865. Most of his life-work was in journalism. He was city editor of the Utica *Herald* for several years, and was afterward editor of the Oswego *Times*. He was for some time Albany correspondent of the New York *Tribune*, and also legislative reporter of the Albany *Journal*. At the time of his death he was editor of the *Cayuga Chief*.—Dr. William J. Scott died on June 18th, at Philadelphia, at the age of thirty-two years. He was born at Bloomsburg, Pa., and was a graduate of the medical department of the University of Pennsylvania in the class of 1892, and also of the Philadelphia College of Pharmacy. He had been a member of the Common Council.—Dr. Lulu C. Fleming died at Philadelphia on June 20th, of sleeping-sickness acquired in medical missionary work in Africa. She was graduated from the Woman's Medical College in 1894.—Dr. Henry G. P. Spencer, of Watertown, N. Y., died on June 27th, in Minneapolis. He was seventy-eight years old, and was graduated from the Jefferson Medical College in 1846.—Dr. James O'Reilly, of this city, died on June 26th. He was born in Ireland in 1828. He first studied for the priesthood but later took up medicine in Dublin. He came to this country about fifty years ago.—Dr. Frederick W. Fabricius, acting assistant surgeon United States army, died at Santiago on June 25th, of yellow fever.

# Reviews and Notices.

TWENTIETH CENTURY PRACTICE. An International Encyclopædia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. In twenty volumes. Volume XVII., Infectious Diseases and Malignant New Growths. New York. William Wood & Co. 1898.

THE "unforeseen difficulties" in the preparation of Volume XVI., which rendered it necessary to issue the present number in advance, have been the means of giving us thus early what in many respects is the most interesting number so far published. The questions brought up in the various articles are all practical and alive, and they have been discussed from a most practical and at the same time strictly scientific standpoint. An enumeration of the subjects will indicate at a glance how very timely the volume containing them seems to be, since they all might be classed under what have been called "burning questions of the day".

1. "Diphtheria—General Pathology and Bacteriology," by William Hallock Park, of New York; "Symptomatology and Treatment," by A. Jacobi, of New York. 2. "Tetanus," by Victor Babes, of Bucharest. 3. "Cancer—General Pathology," by W. Roger Williams, of Bristol, England; "Symptomatology and Treatment," by William B. Coley, of New York. 4. "Sarcoma—General Pathology," by W. Roger Williams; "Symptomatology and Treatment," by William B. Coley. 5. "Malignant New Growths of the Skin," by John T. Bowen, of Boston. 6. "Malignant Diseases of the Female Organs of Generation," by Edward McGuire, of Richmond, Va. Each contributor has done his work not only well, but has presented his subject in an interesting style, the pages being replete with personal experiences which are well calculated to hold the reader's attention. Unlike some works of first magnitude which have burst upon the literary horizon of medicine during the last few decades, this one does not appear to be falling off as the end draws near.

The work of both contributors and editor is deserving of favorable notice, and the latter is worthy of felicitation upon the fact that, if he cannot give us the volume whose number fits into the serial, he at least is usually ready to issue as good a number as the one looked for.

INTERNATIONAL CLINICS. Vol. IV., Eighth Series, January, 1899. Philadelphia: J. B. Lippincott & Co. 1899.

THIS latest volume of the well-known serial to which we have frequently directed attention, holds its own with its predecessors in practical medical and surgical value. Glonoinism is discussed in the first lecture, and those that follow, including the treatment of chancre, corneal ulceration, ulceration of rectum and colon, constipation, cerebral hemorrhage, hæmoptysis, hydrocele, tuberculosis, and many interesting articles on the special branches of medicine, neurology, surgery, gynæcology, ophthalmology, dermatology etc., are of the usual grade of excellence, and give a large amount of useful information in a pleasing, readable form.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia, Physician to the Jefferson Medical College Hospital. Laureate of the Royal Academy of Medicine in Belgium, of the Medical Society of London, Corresponding Fellow of the Sociedad Española de Hygiene of Madrid, Member of the Association of American Physicians, etc. Volume I., March, 1899. Surgery of the Head, Neck, and Chest—Diseases of Children—Pathology—Infectious Diseases, including Croupous Pneumonia—Laryngology and Rhinology—Otology. Philadelphia and New York: Lea Brothers. 1899.

THE scope of this work, of which the first volume is now issued has been set forth in the announcement published during the last few months in all the medical journals. The aim has been to make each editor tell his story of advance in the particular branch entrusted to him, in "a pleasing, easy style, stamped as much as possible by his own personality and modified by his own experience. The staff includes some very well-known names. The advances pertaining to the surgery of the heart, neck, and chest are cared for by J. Chalmers Da Costa, M.D., of Philadelphia, the diseases of children, by Alexander D. Blackader, M.D. of McGill University of Montreal; pathology, by Ludvig Hektoen, M.D., of Rush Medical College, Chicago, infectious diseases, including croupous pneumonia, by William Sydney Thayer, M.D., of Johns Hopkins University, laryngology and rhinology, by A. Logan Turner, M.D., F.S.C.S., Edinburgh, and otology, by Robert L. Randolph, M.D., of Johns Hopkins University, of Baltimore.

The chief objection to the editor's scheme is that one must wait a whole year for the completion of what is in reality a year-book. The subject one wishes to look up will usually be in one of the volumes to come out later. As to the quality of the book, that in the first volume leaves nothing to be desired.

SEXUAL IMPOTENCE: Its Pathology and Treatment. By VICTOR G. NECKI, M.D. From the author's second German edition. Revised and rewritten. Philadelphia: W. B. Saunders. 1899.

THIS work does not follow unswervingly in the footprints of those previously written upon the same subject. The author has preferred his own ideas, drawn from observation, experience, and experimentation, to those views of others which he might have copied from already published sources. To be sure, all the author's theories have not been universally accepted, but the work was read, and a second edition was necessary, and the present English version will undoubtedly receive the attention it deserves.

ESSAYS FOR STUDENTS. By STEVEN PAGET, F.R.C.S., etc. New York: William Wood & Co. 1899.

THIS volume consists of a series of interesting clinical talks, rather than essays, primarily designed for instructing students, but containing matter useful to the more experienced. The first half of the book is devoted to descriptions of cases of various surgical conditions, especially such as are seen in an active hospital practice, and the remainder to an epitome of the methods of examination in aural surgery, with instruction in the pathology and treatment of the conditions most often met with in that branch. The book is entertainingly written, and ought to be useful to the advanced student.

LE TETANOS. Par J. COURMONT ET M. DOYON. Avec quatre figures dans le texte. Paris: J. B. Baillière et Fils. 1899. Les Actualités médicales.

THIS is an interesting little review of the etiology, symptoms, and treatment of tetanus in man and animals, and it contains much up-to-date information. The part which will attract most attention is that devoted to the preparation and use of the antitoxic serum. The instructions are detailed enough to make the book useful in the laboratory, and the author's conclusions are such as will encourage us. We note that it is stated that the serum retains its antitoxic properties for a long time. There is a satisfactory bibliographical index.

ON FRACTURES AND DISLOCATIONS. By DR. H. HELFERICH, of Greifswald. Illustrated with 68 plates and 126 figures in the text, drawn by B. KEILITZ. Translated from the third edition by J. HUTCHINSON, JR., F.R.C.S., Surgeon to London Hospital. New York: William Wood & Co. 1899.

THIS translation of Helferich's work into English certainly adds a very useful handbook to those in our language. The book depends largely for its instructing qualities upon illustrations which are good, and colored plates which are excellent, and upon text descriptions, remarkably concise, considering the Teutonic source. The book is much stronger from the pathological point of view than from the therapeutic, though at least one satisfactory method of treatment is given for each condition. This is, however, not necessarily an objection to such a work and in some ways is distinctly a desirable quality. Many of the plates show more than many pages of text possibly could, and for the student this is a great attraction. On the whole, it forms a very excellent handbook upon the subject of fractures and dislocations, and also a good work of reference although the bibliography of the subject is not gone into to any great extent. The translator's work is, as a rule, well done.

# Society Reports.

## AMERICAN MEDICAL ASSOCIATION

*Fiftieth Annual Meeting, Held at Columbus, Ohio, June 6, 7, 8, 9 and 10, 1899.*

### SECTION ON DISEASES OF CHILDREN.

*First Day—Tuesday, June 6th.*

THE meeting was called to order by the chairman, DR. HENRY E. TULEY, of Louisville, who then delivered the annual address.

**Progress in Pædiatrics.**—Under this caption Dr. Tuley discussed a number of subjects of interest to pædiatricians. He stated that Dr. William Shippen in 1762 had been the first to deliver lectures on the diseases of children. In connection with the advances made in teaching this branch of medicine, reference was made to the recent establishment and endowment of the "Jacobi ward" in the Roosevelt Hospital, New York City, for the clinical study of pædiatrics under that great pioneer teacher, Abraham Jacobi. The "O'Dwyer Memorial," he said, was to take the form of a fund sufficient to stimulate original research in the department of pædiatrics, thus patterning after the life-work of the man whose memory it was desired to perpetuate. In reviewing the subject of infant feeding, it was interesting to note with what unanimity cow's milk had been recognized and advocated as the best substitute for mother's milk. The milk laboratory had come to stay, but there was a useful field for the home modification of milk. For this purpose the method of Dr. W. L. Baner would be found at once simple and satisfactory. Touching upon pneumonia in children the speaker said that lobar pneumonia was now regarded as a self-limited disease, and we had learned that cold was preferable to the use of antipyretic drugs in controlling the hyperpyrexia. He had seen some excellent results from the use of ice in cases of pneumonia. The pulse should be the guide in the use of stimulants. Regarding the diagnosis of pertussis Wagner was quoted as claiming that the diagnosis could be made quite early by bacteriological examination of the nasal secretions. In this disease these secretions contained a natural pure culture of "polbacteria." Some doubt had been thrown recently on the harmlessness of the well-known method of Credé for preventing ophthalmia neonatorum. A number of authors had reported cases in which the two-per-cent. solution of nitrate of silver, instilled into the eyes, had been the cause of a severe conjunctivitis, or had produced a haziness of the cornea. It was possible that protargol and argol might be found efficient and safe substitutes for silver nitrate. The work of various physicians, and notably of Dr. William Cheatham, of Louisville, had raised the question as to the advisability of isolating children suffering from inflammatory conditions of the middle ear, in view of the frequent demonstration, by bacteriological examination, of pneumococci and other cocci in the discharges. In closing, reference was made to the very gratifying statistics, both here and abroad, from the antitoxin treatment of diphtheria, to certain American modifications of O'Dwyer's tubes, and to the interesting observations of Dr. Christopher, of Chicago, with his ergograph, relative to vitality and fatigue in individuals, and their bearing on education.

**The Death-Dealing Long-Tube Nursing-Bottle.**—DR. ERNEST WENDE, of Buffalo, presented a paper on this subject embodying the results of his investigation, by bacteriological, chemical, and microscopical examinations, into the structure of the tubes and the opportunities they afforded for the propagation of germs. He found that the tubes were manufactured from a porous variety of rubber, and that these pores, as well as the seams in the tubes, allowed of the accumulation of coagulated casein, and thereby became the breeding-grounds for bacteria. It was impossible to sterilize such tubes efficiently, and hence the long-tube nursing-bottle should be unreservedly condemned, and its sale prevented as far as possible.

DR. NORBERRY, of Jacksonville, Ind., remarked that there was good reason to believe that the same objections applied to the use of the ordinary rubber nipple.

DR. WENDE replied that of course this was true, but the nipples could be kept reasonably clean, which was not the case with the long tubes. Inquiry had shown that about one in ten of the infants dying in Buffalo of cholera infantum had been fed from the long-tube nursing-bottle. It was significant, therefore, that since the ordinance had been passed prohibiting the use of this form of bottle, the death rate from cholera infantum had been reduced one-half in that city.

**Constipation in Infants.**—DR. H. M. MCCLANAHAN, of Omaha, read this paper. He stated that the real causes of infantile constipation might be conveniently grouped under two heads, viz.: (1) The quantity, quality, and method of feeding, and (2) the anatomical condition of the colon. Under the first group could be classed nine out of the twelve cases forming the basis of his study of this subject. Of this number, seven had been bottle-fed, and all of these children had received food which was deficient in fat. In the two breast-fed babies the mother's milk was about normal in quantity, but there was an excess of casein. Of the three remaining cases the constipation began at birth, and had persisted in spite of treatment continued for months, and in none of these had the constipation been at all influenced by any modification of the food. These latter were apparently cases of anatomical constipation—that variety long ago pointed out by Professor Jacobi. The diagnosis in these cases must be made by exclusion. In the first group the question of regulating the diet was of the greatest importance. The character of the stools should be carefully noted, and when they were light colored and dry the casein should be decreased. In two of the cases the addition of a teaspoonful of malt extract to each feeding was of decided benefit. The general rule was to decrease the casein and increase the fat. When the discharges were coated with mucus, it was advantageous to prescribe the resin of podophyllin in doses of one-fortieth to one-twenty-fifth grain. Another excellent remedy was a saturated solution of phosphate of sodium flavored with lemon juice. In these cases massage of the abdomen and of the entire body was very useful. In the cases of the second class neither food nor medicine was of avail—indeed cathartics were often distinctly harmful. The speaker said that he had no doubt that by gentle manipulation with the finger in the rectum the folds of the rectum could be opened out, thus affording some relief to the constipation in addition to helping in the establishment of the diagnosis. Injections were useful in these cases, and they were best given by passing a lisle-thread catheter through a cork into the bowel for about two inches, the cork being pressed against the anus while the injection was being given. This treatment must be continued for many months.

DR. C. G SLAGLE, of Minneapolis, said that it was particularly difficult to treat constipation occurring in breast-fed infants because of the necessary limitations to modification of the food. With bottle-fed infants the addition of a little sweetened oatmeal water would be sufficient. An important element in the production of infantile constipation he had found to be the com-

mon practice of dosing these little ones with paregoric or various carminative teas, or with castoria.

Dr. Lawrence, of Washington, D. C., said that when there were alternately diarrhœa and constipation the cause was usually to be found in an excess of proteids. Here it was useful to give essence of pepsin, ten or fifteen drops, after nursing, and also to resort to abdominal massage. An excellent plan to secure an action of the bowel at a regular time was by the insertion of an oil-paper suppository. The constipation of bottle-fed infants was very commonly the result of a deficiency of fat in their food, and hence the rational treatment embraced the addition of cream or butter. All forms of teas should be strictly prohibited, and in older children too much potato should not be allowed.

Dr. J. A. Work, of Elkhart, Ind., said that the regular and free evacuation of the bowel presupposed active peristalsis, yet, in his opinion, this free action of the circular muscular fibres of the gut was often materially interfered with by swathing the infant in a tight bandage.

Dr. E. D. Cheseboro, of Providence, R. I., emphasized the part played by fat in securing a regular action of the bowel. Undoubtedly the percentage of proteids exerted a strong influence, but the proportion of fat was equally important. Dr. Holt had pointed out that it was necessary to have a certain excess of fat in the fæces to prevent constipation. Acting upon this hint, he had made it a practice to increase the proportion of fat in the food, and usually with good results.

Dr. Edwin Rosenthal, of Philadelphia, said that it was Dr. Jacobi's custom when lecturing on infantile constipation to exhibit the sigmoid flexure of a child which was eight or ten inches longer than the normal, and to use this as an illustration of what he meant by anatomical constipation. In cases of this kind Dr. Jacobi advised the use of clysters, and stated that it might be three to five years before this part of the bowel came sufficiently near to the normal to put an end to the constipation.

Dr. Harriet E. Garrison, of Dickson, Ill., said that while water was a useful addition to the diet of a constipated infant, it should be remembered that pure water would be chiefly eliminated by the kidney. To obviate this, and to secure its elimination by the bowel, she advised adding a little carbonate of sodium.

Dr. R. C. Moore, of Omaha, also emphasized the importance of increasing the proportion of fat in the food, and instanced as an example of the efficiency of this method the great popularity of the artificial food made according to the old formula of Meigs, of Philadelphia, in which cream was added. If constipated babies having white, lumpy discharges were given orange juice, they would be wonderfully benefited. The orange juice stimulated the natural secretions, thus rendering the stools of proper consistency and of a more nearly natural color. Cod-liver oil was also another very useful remedy in the treatment of infantile constipation. Cathartics were useless, and often injurious.

Dr. Leonard, of Massachusetts, said that under no circumstances did he find it necessary to resort to drugs or to mechanical treatment for the relief of infantile constipation. The food should be of proper quantity and quality, and the interval between the feedings should be at least three hours—longer would be better.

**So-Called Congenital Obliteration of the Bile Ducts.**—Dr. Frank X. Walls, of Chicago, read a paper with this title. He stated that Thompson had analyzed forty-nine cases of this kind, all terminating fatally, and had concluded that in the great majority there was at first a congenital malformation of the bile ducts, the result of defective development. This, the speaker said, had been assumed rather than demonstrated. The unequivocal evidence of biliary obstruction, *i.e.*, jaundice, had not been observed in a large proportion of the cases until at least a week after birth. This fact seemed to indicate pretty conclusively that the ducts at birth were patent. He was inclined to look upon these cases as examples of catarrhal gastro-duodenitis. In the adult, probably as a result of irritation of the intestinal canal and bile passages, a homogeneous plug became attached to the basement membrane, and completed the occlusion of the ducts. After the removal of the irritant the biliary flow might be re-established. In the case of the infant this plug did not seem to be dissolved, probably because of the absence of a proteolytic ferment. If this last theory should be adopted, all of the other phenomena observed would be easily explained. The aim of treatment should be to prevent irritation of the gastro-intestinal canal after birth, and surgical exploration was indicated as soon as the diagnosis had been established, followed by dilatation of the ducts or the establishment of an anastomosis between the intestinal and biliary tracts. Congenital biliary occlusion, the speaker said, was a misnomer; in the majority of cases there was an inflammatory condition followed by an obliterating angiocholitis.

Dr. Slagle said that he had many times met with cases in which there had apparently been obliteration of the ducts. By alkaline baths, massage, and the administration of phosphate of soda a great deal of good could be done.

**Some Thoughts on Physiological Elimination in all Pathological Conditions.**—Dr. J. A. Work, of Elkhart, Ind., read this paper, which was a philosophical essay designed to show the bearing of physiological elimination on the course and treatment of acute zymotic diseases, and on surgical operations. He asserted that the typhoid-fever patient often had to contend with three foes, viz.: sepsis, the specific germ infection, and the effect of needless and unwise medication.

Dr. E. E. Mayer, of Pittsburg, said that, while the general statement was true that physiological elimination was the basis of treatment, if this line of reasoning was to be pushed very far one would be in great danger of wandering from true science and disregarding the advances that had been made during the last quarter of a century in bacteriology, chemistry, and pathology. If one desired to treat disease strictly by physiological elimination, then it would be well to follow the advice of Oliver Wendell Holmes, and begin to treat the child by treating its grandmother. A proper appreciation of physiological psychology and physiological chemistry, in the way of treating the antecedents of the child, would do more than physiological elimination in the child itself.

Dr. Work said that chemical force was ever ready to take advantage of vital force. As an initiative procedure in all cases he would employ physiological—not pathological—elimination, just to arouse nature to her sense of duty.

**Infantile Diseases from the Standpoint of Biology.**—Dr. Joseph Clements, of Kansas City, in this paper discussed vitality, and the relation of the nutrition of the cells to the processes going on in the system, both in health and in disease.

---

*Second Day—Wednesday, June 7th.*

**Hysteria in Children.**—Dr. E. E. Mayer, of Pittsburg, read this paper. He said that hysteria in children had been first described in 1748. This affection might be described as a discharge of morbid influences along the various motor and sensory paths. Improper home influences and training certainly promoted such

abnormal motor states. The brain was a passageway as well as a storehouse. The volitional centres were but little developed in children, while the imaginative ones ran riot. The well-known hysterical stigmata—the anæsthesiæ and the hysterical zones present in hysterical adults—were usually absent in children. Hysterical children were generally precocious, egotistic, emotional, and moody. Hysterical palsies were characterized by rapid and marked variations in character, and by frequent relapses. Hysterical stuttering was also often observed. Camp-meetings and spiritualistic séances were potent etiological factors. In beginning the treatment of such a case the patient should be placed in a hospital and an effort made so to occupy the child's time that there would be no time to be sick. If paralyses were present the child should be placed in a suspension apparatus, and made to walk, and while doing so should be suddenly dropped upon the feet.

Dr. Slagle expressed doubt about idiopathic hysteria being so common in children of seven or eight years as it had been represented to be. As a symptomatic affection, however, it was not uncommon. A practical point to which he directed attention was the liability of inducing hysteria in certain debilitated subjects by the administration of strychnine. In one instance in which he had been giving this drug to a young girl because of a weak heart associated with convalescence from typhoid fever, it had been a long time before he had discovered the cause of the hysteria.

Dr. Rosa Engelman, of Chicago, cited two or three interesting cases of hysteria occurring in children, including a case of hysterical joint disease associated with marked and persistent polyuria.

Dr. Gustav Blech, of Chicago, spoke of a case of hysterical aphasia that he had seen in a boy of four years.

Dr. Harriet Garrison said that, judging from an experience in a small town, she would say that hysteria was quite common among children. She had under her care at present a severe and obstinate case of hysteria that was dependent upon the administration of strychnine. It had been a long time before she had discovered the true cause, and then she had learned that every time the woman took a dose of strychnine she had a convulsion. On stopping the strychnine the convulsions ceased.

Dr. Slagle remarked that the best of all treatment for hysteria was hypnotism.

Dr. Garrison replied to this that, in her opinion, the best of all treatment was preventive, and consisted in teaching the parents to discipline their children properly.

Dr. Mayer, in closing the discussion, declared it to be his opinion that hypnotism was the worst of all methods of treating hysteria, and that, although formerly much in vogue in Paris, it was even there being quite generally discarded.

**Infantile Convulsions; Their Cause, Nature, and Management.**—Dr. C. G. Slagle, of Minneapolis, in this paper classified the various kinds of eclampsia occurring in children. He said that the transition from eclampsia to epilepsy seemed, in some cases, very easy. In some instances, convulsions indicated nothing more than a mode of dying, as in such diseases as cholera infantum, in which there were profuse watery discharges. A temperature much above 103° F, and lasting for several hours in a neurotic child, was very liable to induce convulsions. He was of the opinion that there existed in some children what might be very aptly termed "a convulsive tendency." One of the most severe cases of eclampsia that he had ever seen in a child had followed as a result of a bad scald. Opinions differed as to the influence of dentition on the production of eclampsia, but personally he could hardly recall a case in which it had seemed that the eclampsia had been fairly attributable to the eruption of the teeth. A safe rule to follow was, that dentition should not be considered as a possible cause until all others had been excluded. Probably one-half of all the cases occurring in young children could be traced to improper feeding.

Dr. A. C. Cotton, of Chicago, said that at the last annual meeting he had presented a paper entitled "Disturbed Lactation; Some Causes and Effects," in which he had directed attention to the not infrequent occurrence of convulsions, apparently as a result of the discontinuance of lactation. While the supposition was that in infants at the breast dietetic errors as a cause of convulsions could be eliminated, there were good grounds for the belief that this was an error, and that the breast milk was subject to sudden and violent fluctuations in quality. These might result from mental, hygienic, climatic, thermal, and many other influences. He had continued his observations during the past year along this line, and with the greatest care. He thought there was good evidence for believing that not infrequently undue, unusual, or excessive coitus in a nursing woman would so change the quality of the breast milk as to give rise to marked disturbance in the nursling, such as convulsions, or even, in exceptional instances, death.

Dr. Kimball, of Indiana, said that in the treatment of infantile convulsions he had derived special satisfaction from the administration of gelsemium. By its action on the cerebro-spinal centres it seemed to control the convulsion more quickly than anything else, and it was easily given.

Dr. Ewing, of Salt Lake City, said that in male children he had found an adherent prepuce a common cause of convulsions.

Dr. Foster, of Illinois, said that some physicians used stimulants and others depressants in the treatment of convulsions in infants, yet the profession did not seem to be agreed as to the pathology of the condition—as to whether the nerve cells of the brain were stimulated or depressed. Personally he believed that in the majority of cases the nerve cells were depressed, and his management of such cases was in accordance with this view.

Dr. Slagle, in closing, said that the spasm was best controlled by the inhalation of chloroform. It was always well to give an enema of salt water, both for its revulsive effect and evacuant action. It was also desirable in very many cases to give an emetic, particularly in those cases in which from the history it seemed probable that the undigested food had not yet passed beyond the stomach. He thought he got just as good results from enemas of salt water as from enemas containing bromide. Adherent prepuce was certainly a contributory cause, but he doubted if it was an exciting cause.

**Comparative Therapeutic Value of Recent Antiseptics in Pædiatric Practice.**—Dr. Gustavus M. Blech, of Chicago, read this paper. He said that the antiseptics of use in pædiatric practice could be divided into four classes, viz.: (1) Those which acted on the respiratory tract; (2) those acting on the gastro-intestinal tract; (3) those affecting the urinary apparatus; (4) those which influenced the whole organism. Urotropin was decomposed by the urine, and destroyed the bacteria in this fluid. Guaiacol carbonate was a comparatively tasteless and non-irritating antiseptic, very useful in the treatment of chronic bronchitis. Tuberculosis could be cured in its first and second stages by the antitoxic treatment, but drugs had but little curative effect in the later stages of this disease, and Murphy's nitrogen treatment had already proved a total failure. Nosophen had

been proved to be a harmless drug. Antinosin had been used in solution of 2.5 per cent. strength without producing irritation. He used it exclusively as a disinfectant and cleansing solution in the nasal passages. Eudoxin, the bismuth salt of nosin, was an excellent remedy in diarrhœa. Experiments had proved that by the action of the gastric juice stable salts of bismuth were formed. The nosophen contained in eudoxin passed on unaltered. In two cases of typhoid fever in which he had used eudoxin the stools had been rendered aseptic in about three days.

Dr. Edwin Rosenthal said that he had often prescribed for infants salol in doses of 1 gm. without observing any unpleasant effect.

Dr. Slagle said that of the many antiseptic remedies in use internally he did not consider more than three of much value. They were calomel, sulphur, and sulphite of soda.

Dr. Cotton said that he had not used the newer antiseptics very extensively, but his experience with eudoxin had been so encouraging that he proposed to employ it in the future still more frequently. He would probably not live long enough to outgrow his predilection for calomel as an intestinal antiseptic. He had used guaiacol with satisfaction both locally and constitutionally. Liquid guaiacol had served a good purpose in his hands when applied to the tonsil, and he still continued to use the guaiacol carbonate internally.

**Treatment of Septic Conditions in Children.**—Dr. Edwin Rosenthal, of Philadelphia, read a paper with this title. The paper was devoted chiefly to a consideration of the treatment of septic processes by the use of antistreptococcic serum. It was best given, he said, in a large initial dose when the temperature began to rise. It had been found to be a wholly harmless remedy in any quantity. The ordinary initial dose was 20 c.c. It had been proved that this serum could be given with advantage in immunizing doses before operations which were especially liable to be followed by sepsis. He advised using the serum in all suspected cases of septic infection, and as an immunizing agent in the class of cases just mentioned.

Dr. Dillon Brown, of New York, expressed surprise at Dr. Rosenthal's great confidence in the antistreptococcic serum, for it did not seem to him possible that any serum could be of benefit in this class of cases, as there was not a pure toxæmia.

Dr. Blech said that he had seen very favorable result from the use of a good antistreptococcic serum, and reliable authorities had reported many cases in which the temperature had rapidly fallen after the first or second injection of the serum.

Dr. Rosa Engelman said that her rather limited experience with this treatment had been, on the whole, favorable.

Dr. A. C. Cotton counselled patience in waiting for, and duly weighing, the reported results from this new treatment. He believed it was the duty of every physician in the present state of our knowledge to use the antistreptococcic serum in every case that seemed appropriate.

Dr. Rosenthal, in closing the discussion, said that before the use of antistreptococcic serum operations on the tongue and mouth were almost invariably followed by septic pneumonia, but now in cases receiving immunizing doses of the serum before operation this septic pneumonia was wholly unknown.

**Membranous Tonsillitis and Pharyngitis of Influenza.**—Dr. Rosa Engelman, of Chicago, read a paper with this title. She stated that she had succeeded in demonstrating the presence of the Pfeiffer germ in numerous cases among those on which the present communication was founded. The clinical appearance of the throat had often been like that of diphtheria, but had been differentiated therefrom by bacteriological examination. A case was cited illustrating the clinical features.

Dr. Rosenthal said that he had noted a similar appearance in the throat in cases of influenza, and Finkler claimed that it was present in 80 per cent. of the cases. On comparing the appearance of the throat in grippe and diphtheria it would be noticed that the grippe cases presented a granular appearance which was quite characteristic.

Dr. Stevens, of Detroit, spoke of some of the difficulties of making a correct differential diagnosis in cases presenting a membranous exudation in the throat, and the disagreements that often arose between the skilled clinician and the expert bacteriologist.

Dr. Davis, of Pittsburg, objected to this splitting of hairs in making the diagnosis of diphtheria, particularly as in those days it often entailed unnecessary hardships on the family by imposing upon them a rigorous and unnecessarily prolonged quarantine.

Dr. Cotton said that he had learned that von Jaksch had made nearly two hundred examinations on typical cases of influenza during the past winter, with the result that the Pfeiffer bacillus had been found in less than ten per cent. Clinical diphtheria was a thing of the past; there was no diphtheria except the pure and simple Klebs-Loeffler diphtheria, a rather rare disorder, and one that was certainly amenable to treatment. He was heartily in favor of the early use of diphtheria antitoxin, and if the symptoms did not promptly abate he would use the antistreptococcic serum.

Dr. Engelman, in closing, said that she had been unable to differentiate her cases of grippe from those of diphtheria by the appearance of the membranous exudate. Many cases of follicular tonsillitis during the past two years which had appeared clinically as tonsillitis had been proved by bacteriological examination to be Klebs-Loeffler diphtheria. Differences of opinion among bacteriologists regarding the diagnosis in a given case often arose from looking at the culture at different stages of its growth—at different hours. A few years ago it had been asserted very positively that there was no diphtheria but the Klebs-Loeffler diphtheria, yet at that time she had reported several cases in which intubation had been demanded, although it had been impossible to demonstrate the presence of the Klebs-Loeffler bacillus. We knew now that it was possible that these cases were examples of infection with the bacillus lanceolatus or pneumococcus.

**The Semeiology of the Attitude and Motor State in Children.**—Dr. S. W. Kelley, of Cleveland, presented a communication with this title. He said that disease in children was often manifested first by lessened vitality during the waking period, or by restlessness during sleep. The position in bed was also significant. The well-known apprehensiveness of the child just before a paroxysm of whooping-cough was not observed in that very similar state in which a spasmodic cough resulted from enlargement of the bronchial glands. An attitude upon the side, with the head retracted and the lower extremities drawn up, was often seen in the later stages of tuberculous meningitis. If the child lay with its head turned persistently toward the wall one would suspect inflammation of the eye, or some inflammation of the meninges. If it lay persistently on the side one would suspect pleurisy or pneumonia; but if, in a case of pleurisy, there was much effusion, the child might instead assume the dorsal decubitus. The dropping of the head forward on the breast was sometimes indicative of the paralysis which follows diphtheria. He had more than once seen rigidity of the muscles about the jaw from overdosing with nux vomica. The knee-jerks were diminished or absent in paralyses of spinal origin. It was

well to distinguish between true paralysis and the listlessness of marasmus.

Dr. Slagle said that there had been recently in his city an epidemic of typhoid fever in which the predominance of the brain symptoms had greatly puzzled the physicians in the early stages. These cases tallied exactly with what had been described as "meningitic typhoid fever." When these meningitic symptoms had passed away there had been no difficulty in recognizing the typhoid fever.

Dr. Kelley said that the great object in writing this paper had been to emphasize the fact that physicians should not forget how to use their hands and eyes, and to interpret what they discovered in this way, even though they had at their disposal many instruments of precision unknown to the skilled diagnosticians of old.

*Third Day—Thursday, June 8th.*

**Septic Conditions in Some Acute Disorders of Children.**—Dr. A. C. Cotton, of Chicago, read a paper with this title. This communication was essentially a clinical one, being largely a narration of cases selected from the author's case-books. He said that streptococcus pneumonias had been unusually prevalent during the past year in his city, and had been associated with otitis media in about seventy-five per cent. of the cases. The paper advocated advanced views regarding the zymotic disease, and especially a reform of the old and indefinite nomenclature. It elicited a general discussion on the advisability of making such changes in the terminology, and while the consensus of opinion seemed to be in favor of these changes, the more conservative thought the very object of such a reform would be frustrated if these advances were too sudden and sweeping.

**The Grippe Exanthemata.**—Dr. Harriet E. Garrison, of Dixon, Ill., read this paper. She said that during the past winter the people of her locality had been greatly interested in the decision of the question as to whether the cases of exanthemata which presented themselves were both scarlet fever and measles, or whether they were different forms of the same exanthem. A case was related in which the symptoms had been apparently those of rubella, or German measles. There was a profuse eruption like that of measles, without much constitutional disturbance, and convalescence had been well established by the following day. About this time an epidemic of grippe had developed. The second case, seen a few days later, had resembled scarlet fever very closely. There had been still another variety of the eruption, characterized by the presence of numerous papules, and its association with severe pruritus. Dr. Garrison said that she had attended two or three hundred cases of grippe and had seen otitis media in only about one-tenth of them. Apparently in the cases detailed the exanthem was simply a sequel of grippe. Sometimes the eruptions recurred after six or eight weeks, but the recurrence was always preceded by the symptoms of grippe.

Dr. Slagle was inclined to the opinion that there had been an epidemic of German measles prevailing along with the grippe, and that the diagnosis in some of the cases had been more or less obscured by the simultaneous use of acetanilid.

Dr. I. N. Love, of St. Louis, said that our knowledge of the infectious diseases seemed to justify the view that the majority of them were at times associated with rashes. Such eruptions were apparently only manifestations on the integument of some specific effect on the nerve centres produced by the toxin of the infectious disease. A similar epidemic to the one described had prevailed in St. Louis. He had seen an enormous number of cases of rubella. The bacteriological examination showed in the secretions from many of the cases of rubella the presence of the grippe bacillus. The fact had not been sufficiently recognized in the past, that grippe was an infectious disease which was peculiarly liable to attack children, and which was dangerous through its complications and a neglect to treat them properly.

Dr. Joseph Clements, of Kansas City, remarked that when the fact was appreciated that diseases consisted of vital phenomena equally with health, then a nomenclature could be adopted which would not be misleading either to physicians or to the laity.

Dr. Garrison, in closing, said with reference to the use of acetanilid that in the cases in which this drug had been given most freely no rash had appeared.

**Treatment of Scarlet Fever.**—This paper, by Dr. R. B. Gilbert, of Louisville, was read, in his absence, by Dr. Solomon. It stated that Dr. E. M. Landes, of Chicago, had recently reported a case of scarlet fever which he had successfully treated by two injections of antistreptococcic serum. The treatment should consist chiefly in guarding against infection, controlling against hyperpyrexia, attending to the consequent anæmia and to the complications. It should be remembered that the danger of infection was as great in the mild as in the severe cases. Not only should the patient be isolated, and the room be stripped of all unnecessary hangings and furniture, but dogs and cats should be carefully excluded. If the skin was kept thoroughly anointed with lard, vaseline, or lanolin the danger of infection during the stage of desquamation would be materially reduced. Moreover such applications were soothing, and tended to reduce the fever. Clothing and bedding could be best disinfected by subjecting them to the action of boiling water or live steam for a few hours. A temperature above 103° F. should be regarded as dangerous because of the disturbance of the nervous system and glandular organs. He had abandoned the use of the coal-tar antipyretics because he had found that they produced dangerous cardiac depression. The patient should drink cold water freely. The depression and shock which followed the use of the full bath were sometimes considerable, and hence it should not be employed except when there were very high fever and violent delirium. The nose and throat should be sprayed with a mixture of equal parts of hydrogen dioxide and lime water. For the control of restlessness at night chloral hydrate was useful. Opiates should be avoided because of the danger of exciting nephritis. Iron in some palatable form should be given from the outset in all cases of scarlet fever, to prevent the anæmia. He preferred to use the ammonio-citrate of iron, in doses of one grain. The patient should be nourished by the use of soup, milk, and similar foods.

Dr. Quayle, of Madison, Ohio, said that he preferred that the ointment used for anointing the body should be carbolized. It was his custom to prescribe lithia water as a mild stimulant to the kidneys, and to flush the bowel with warm water. He avoided such antipyretics as acetanilid, and was guided in the use of diaphoretics by the stage of the pulse. He prescribed the peptomanganate of iron for the anæmia.

Dr. Slagle objected very strongly to giving scarlet-fever patients antipyretic drugs, quinine, and iron. Cold water should be the chief therapeutic agent in this disease—just the opposite of the treatment for measles. The child should be given cold water, cold lemonade, cold enemata, and cold packs. The inunctions certainly reduced the temperature.

Dr. Ewing, of Salt Lake, said that his rule was to use eliminatives, such as acetate of potassium and liquor ammonii acetatis, in scarlet fever, with the object of washing the toxins out of the system. The free

ingestion of water was also important for the same reason.

Dr. Garrison said that for about eight years she had been using acetanilid freely in scarlet fever, and with the happiest results. The only unpleasant effect ever noticed had been a diminution of the quantity of urine, but even this had been entirely avoided by combining a little bicarbonate of soda with the acetanilid. Cold water was good, but the acetanilid was better, for it quieted the restlessness and made the patient feel a great deal better. Since adopting this treatment she had lost all fear of scarlet fever, had not seen otitis media, and did not expect to have any complications. Many of the cases had been severe.

Dr. Slagle remarked that he was afraid that she had not encountered any cases of scarlatina of the malignant type.

Dr. Bell, of Illinois, a health officer, inveighed against physicians as well as the laity for their great carelessness regarding the proper quarantine of scarlet fever, and for their lack of co-operation with the health authorities. In the mild cases acetanilid would do good; in the malignant ones nothing would do any good.

Dr. Solomon, of Louisville, said that for the severe headache and joint-pains the antipyretics, such an acetanilid, were beneficial, but for the muscular pains he preferred phenacetin. When the pulse was of high tension he preferred antipyrin, and never feared to give it to the youngest infant in doses of one-fourth of a grain. It favored elimination by inducing perspiration. Baths frightened many infants; moreover cold applications by contracting the cutaneous vessels tended to produce internal congestion—something which should be avoided because of the tendency in this disease toward congestion of the kidneys. He often prescribed scoparius to relieve the passive congestion of the kidneys, and in doses of one teaspoonful of the decoction it acted admirably. He also favored the use of cholagogues, such as phosphate of soda and cascara.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, June 1, 1899.*

William H. Thomson, M.D., President.

**Treatment of Summer Diarrhœa in Infants.**—Dr. Henry D. Chapin read a paper on this subject. He divided its consideration into three parts, viz.: (1) The preventive treatment; (2) the dietetic, and (3) the medicinal. Too frequent feeding was asserted to be a common underlying cause of infantile indigestion, and the giving of too large a quantity of food in the bottle is another factor. In hot weather fermentation of the food, added to the depression of the infant's vitality resulting from the heat, gave rise to summer diarrhœa. In this locality July gave much the highest death rate. By the time that July arrived there had already been several weeks of continuous heat. Infants under two years were the greatest sufferers, but preventive treatment, if properly carried out, would do much to mitigate this veritable scourge. Cleanliness of the city streets and watchfulness of perishable food products were important sanitary measures. If the dairy could be properly supervised and the milk delivered to the city consumer within twelve hours after milking, there would be very little summer diarrhœa. Another way that the city could help in this work was by providing parks and planting many shade trees in the streets. It had been shown by Dr. Stephen Smith that the most healthful average temperature was 54° F. Extra cleanliness in the domicile was equally important. The milk should be pasteurized or sterilized, and then placed on the ice. Diapers should be removed as soon as soiled and placed in a solution of chloride of lime. The rooms were often kept needlessly warm by a lack of attention to the exclusion of sun and letting in the fresh air. Babies were frequently too warmly clad. Day excursions to the seaside were useful, but in considering them due weight must be given to the possible harmfulness of fatigue and improper care of the food taken on such trips. As the maximum heat occurred between the hours of two and five o'clock in the afternoon, it was often well to direct that the little ones be allowed to play in a bath-tub in tepid water for two or three hours during this hottest part of the day. In his experience, pasteurization or sterilization of milk was largely unnecessary, unless perhaps for a short time in very hot weather. During an attack of acute summer diarrhœa, bearing in mind that the majority of these cases were really examples of milk poisoning, milk should be excluded, and very little nourishment given. It was folly to force milk upon a baby at a time when its digestive powers were weakened or arrested. When it was necessary to withhold milk for any length of time, egg water might be used. It could be made by stirring the white of a fresh egg in a glass of cold water, and to overcome the tastelessness it was well to add a few drops of aromatic spirits of ammonia. Thin gruels made from barley or wheat flour and cold whey were also useful substitutes for milk. When cow's milk had to be excluded for several days, mutton broth with the fat removed would be found a useful addition to the diet. The resumption of milk must be tentative, and the milk given at long intervals and diluted five or six times with sugar water. He had made a series of laboratory experiments recently upon a dog with a gastric fistula, using liquid rennet and various mixtures, such as milk and water and milk and barley water. Some physicians objected to the addition of cereals, on the ground that they were too prone to ferment, but this could be entirely overcome by using some good preparation of dextrin. Astringents, antiseptics, and opiates were now but little used in the treatment of summer diarrhœa. A prerequisite to success was a thorough cleaning out of the intestinal tract. If there was much vomiting, draughts of tepid water might be given; and when rejected they would sufficiently wash out the stomach without resort to the stomach tube. He was accustomed to clear out the bowel by the administration of tablet triturates of one-tenth of a grain of calomel, given every hour for six or eight doses. Castor oil was also useful. Irrigation of the lower bowel with decinormal salt solution would favor elimination, and would secure the removal of mucus and fermenting milk. The drug that he had found most useful was the subnitrate of bismuth in large doses. A baby of six to twelve months could take ten to twenty grains of subnitrate of bismuth every two or three hours. He had seen no advantage in using the other preparations of bismuth. Most of the so-called antiseptic remedies had irritating qualities, and on this account should not be used, or used only very sparingly. Small doses of aromatic spirits of ammonia would stimulate the mucous membrane and refresh the infant. He gave alcohol very sparingly now in these cases, as it seemed in most instances to diminish the digestive power. Of course, when there was great prostration free stimulation would be required. Opium should never be given combined with other drugs—indeed, diarrhœa mixtures of all kinds were to be deprecated. Opium should not be given until the alimentary tract had been cleared out. When there were rapid peristalsis and profuse glandular secretion a few doses of opium were most valuable, and would sometimes save life.

**Disseminate Information among the Ignorant.**—Dr. L. Emmett Holt said that he thought more stress might be laid upon one means of prophylaxis, *i.e.*, the dissemination of literature in the tenements. These people were grossly ignorant of all dietetic matters, and especially regarding infant feeding. The experiments described by Dr. Chapin did not seem very conclusive. In his opinion, the clinical fact was well established that dilution of the proteids of milk with some kind of carbohydrates did have a very advantageous effect on digestion. The best and most careful work on this subject had been done by Arthur Keller. The carbohydrates, merely by their presence, seemed to prevent largely the putrefactive decomposition of the proteids of milk. The most common mistake made in private practice was to temporize during the first few hours with a case of summer diarrhœa, the child not appearing to be very ill. The rule should be to stop food at once and completely. The condition was primarily one of acute intoxication; hence the stomach and intestine should be evacuated as soon as possible.

**Irrigate the Bowel Often.**—He would lay stress on the value of irrigation of the bowel in bad cases four or five times daily. The presence of fluid in the colon would cause a contraction of the ileum, and within a short time the colon would be again filled with material from above. The water should be at first at a temperature of 100° F. or a little higher. Before finishing the irrigation it might be well to allow the temperature to sink as low as 75° F. Instead of giving these children food they should be given small quantities of sterile tepid water at short intervals. The later treatment of these cases was always unsatisfactory. One fact often overlooked was, that sterilized milk did not long remain sterile when put into an intestine that was already infected; hence sterilized milk must be excluded also in these cases.

Dr. A. Jacobi said that it was a great satisfaction to him to hear the previous speakers bring forward and indorse certain truths that he had been teaching for the past thirty years. The admixture of milk and barley water certainly did improve the flocculency of the curd. This teaching was gradually gaining ground, as was shown by the literature from abroad. Twenty-seven years ago the board of health of New York City had printed in different languages and distributed leaflets giving much needed information to the poor regarding the care and feeding of infants, particularly during the heated term. He had been responsible for the information contained in these leaflets, which had been distributed up to a very few years ago. He had originally advised that the milk should be boiled with a little bicarbonate of sodium, but he now considered this a mistake, because this alkaline fluid afforded a better culture medium for the bacteria. The statement had been made that a German observer had recently discovered that the cereals, by their presence, prevented putrefaction of milk, but this was not new, as he had seen it mentioned in books many years ago. The acids of the cereals accomplished in the lower part of the intestine what the hydrochloric acid did in the upper part.

**Starch and Infantile Digestion.**—The old objection to these cereals that they contained starch, and that the starch could not possibly be digested by a young infant, was now known to be untenable. Even granting, for the sake of argument, that it was so, it was of no importance, for even if a little starch was left undigested in the intestine it would do no harm; there were many other things in the intestine which were not digested. For instance, the normal fæces of a healthy breast-fed baby contained from eight to twelve per cent. of undigested fat. But it had been known for twenty-five years that starch could be digested by a very young infant; many experiments had demonstrated that the saliva of such an infant could digest the starch, and particularly the starch of oats and barley. The parotid gland of the healthy fœtus contained a material for dextrinizing starch. The pancreas, it was true, did not begin this function until the child was one month old, and it was not fully developed for two months more.

**Rapid Cooling after Sterilization.**—Dr. H. Koplik laid still greater stress on the preventive treatment, and asserted that the dietetic management alone was often sufficient to check a summer diarrhœa in its incipiency. He was surprised that the reader of the paper had brushed aside so lightly the sterilization of milk. If the milk could be brought quickly to the consumer it would be all very well to pasteurize it and keep it on the ice, but these conditions could rarely be fulfilled, and hence in the summer the milk should not only be sterilized, but it should be rapidly cooled, as he had recently learned that this rapid cooling largely prevented the separation of the fat. He agreed with the other speakers as to the value of cereals, but stated that they were not tolerated by many infants. The great point was to give the nourishment highly diluted. He had been surprised at the popularity of calomel for the preliminary emptying of the gut, as he had been afraid that its action on the kidneys might be prejudicial. Castor oil was good enough for him. He would never advise the use of opium in summer diarrhœa.

**Supply Water to the System.**—Bathing was a useful prophylactic, but the principal thing in the actual treatment of the condition was irrigation of the bowel, for it not only stimulated peristalsis and cleansed the gut, but supplied to the system the water so rapidly lost. The stiff rectal tube would be found the most convenient for this purpose, and the reservoir of fluid should not be more than one or two feet above the patient's body. It was well to leave a pint or more of decinormal salt solution in the bowel.

**Pasteurization Not Sufficient in Summer.**—Dr. Walter Lester Carr said that in the preventive treatment nothing was so important as the complete withdrawal of milk. If this were done, the return to diluted milk could be made much more quickly than if diluted milk had been allowed for a time at the beginning. Perhaps the next measure in importance was the irrigation of the bowel with decinormal saline solution. In a certain number of instances pasteurized milk did not do so well as sterilized milk in summer.

**Nutritive Value of Dextrose.**—Dr. Graham Lusk said that about five years ago he had done some experimental work in his laboratory in conjunction with Dr. Sanford. One young pig had been fed on skimmed milk alone; another on milk containing two per cent. of sugar, and a third pig had been fed on a similar quantity of milk containing dextrose. The first pig had remained thin and poorly nourished. The second pig had increased in weight, while the third pig had done very much better than the other two. Dextrose itself, which was the normal blood sugar, was useful in the young animal. This dextrose could be obtained from the dextrins themselves, as illustrated in the experiments referred to by Dr. Chapin.

Dr. Chapin closed the discussion. He stated that in his experience the majority of infants tolerated milk diluted with the cereals much better than when it was diluted with water alone. The digestion of babies fed for many weeks on sterilized milk was not so good as when they were fed on pasteurized milk, but after all the great advance of the future would be in securing fresh and clean milk.

SECTION ON OBSTETRICS AND GYNECOLOGY.

*Stated Meeting, May 25, 1899.*

BROOKS H. WELLS, M.D., CHAIRMAN.

**Removal of a Kidney and the Whole Ureter for Tuberculosis.**—DR. E. J. ILL, of Newark, presented a kidney which he had just removed by operation from a woman who one year ago had begun to suffer from pain in the left groin, radiating into the left iliac fossa. Last February she had begun to be troubled with painful and frequent micturition, but it had not been until three weeks ago that the urine had been examined for tubercle bacilli, and these organisms had been found. Two weeks ago she had come under his care, and examination had shown a few tuberculous ulcerations in the bladder, and a swelling and thickening about the left ureter. To-day he had removed the diseased left kidney through a horizontal incision, about four inches in length, located in the flank. By a supplementary incision the ureter had been followed as far down as the ovarian artery, and then it had been severed with a cautery after having been ligated on either side of the point of section. The application of the ligatures had been facilitated by an incision through the vagina. The insertion of the ureter in the bladder had been reached by dragging on the lower ligature. It had then been ligated and sewed into the vagina, so that practically all of the ureter had been removed down to the bladder. Through these two small incisions he had followed the whole course of the ureter with ease.

DR. BALLERAY presented several tumors. The first one had been removed from the clitoris and nymphæ by ligation and excision. The tumor was cystic, but its exact nature had not yet been determined. The second tumor was a lipoma removed from the thigh. The third was a blood cyst of the ovary that had formed quite rapidly. The patient had stated that she had flowed more profusely than common at her last menstruation, and that there had been an irregular flow once or twice since that time. When first removed the tumor had been a translucent cyst filled with bloody fluid. The next specimen consisted of the tubes and ovaries from a case in which the adhesions had been extensive, and after separating them there had been so much trouble in controlling the bleeding that he had been on the point of removing the uterus. The ovary contained a small abscess. The next specimen was a small fibroid tumor. The speaker said that he had seen eleven cases of fibroids within the past three months. In several of these, although the growth had been quite small, the hemorrhage had been remarkably profuse. Another specimen was a pyosalpinx which he used as a text for a plea that these cases should be operated upon before there had been one or more attacks of peritonitis. The patient from whom this specimen had been taken had been using large quantities of morphine at the time of the operation, but within two weeks this habit had been entirely stopped. The last specimen was a large fibromatous uterus removed from a woman who until recently had not been aware that she was carrying any abdominal growth. She was a large woman, weighing about two hundred pounds. She had always menstruated freely, but had been in good health up to an attack of acute peritonitis, at which time he had first seen her. As soon as the inflammation had subsided, the mass had been removed by a supravaginal amputation.

DR. ILL said that he understood that the last specimen—the large fibroid tumor—had been removed simply because it was a tumor, although it had given rise to no symptoms. He had himself always carefully avoided this, and proposed to continue this practice, although he was quite well aware that certain good authorities had declared that they had observed that benign tumors subsequently became malignant. He had never observed this himself, and was very sceptical about its occurrence.

DR. BROOKS H. WELLS said that years ago, when the mortality from operations on fibroids was very high, surgeons had abstained from operating unless the symptoms were urgent; but now, when the mortality was reduced to about two per cent., it was justifiable to remove these growths for much slighter indications than formerly. Some authorities went so far as to claim that every fibroid should be removed as soon as discovered. This he would not subscribe to, although it could not be denied that the course of a fibroid was very uncertain. If the patient was intelligent and could be kept under observation it seemed to him preferable to avoid operation unless the tumor began to grow rapidly or gave rise to profuse hemorrhage or marked pressure symptoms. He had recently seen three cases in which death had resulted because the patients had been told years ago that their fibroids did not require operation, and had been advised not to allow any one to operate on them. On the other hand, he had in mind three cases that he had observed for some time. These women had passed the menopause, and the slight hemorrhage and pain that had previously existed had now ceased. If, therefore, a tumor gave rise to hemorrhage or began to grow rapidly, his opinion was that the sooner it was removed the better.

**Dangers of Vaginal Operation for Fibroids.**—Dr. Wells then exhibited a small submucous fibroid which had been removed from the uterus of a woman who had been troubled for some time with severe and persistent hemorrhages. When he had first seen her she had been forty-three years of age. Menstruation had recurred every two weeks, so that there had been scarcely any cessation in the bleeding. She had refused operation for two years, and by that time she had become exceedingly anæmic. The tumor had then been removed from the fundus of the uterus through an anterior vaginal incision, aided by morcellation. When it had been taken out the shell had been exceedingly thin and friable. The risk of removing these tumors by morcellation lay in the liability to tear through this wall and open into the peritoneal cavity. If this accident should occur, the safest plan was to remove the uterus. The second danger was from hemorrhage. In the case referred to, careful search had been made, in a good light, for bleeding vessels, but none of importance had been found. However, after she had been taken back to bed, and had been there for two or three hours, she had suddenly begun to bleed and had gone into collapse. Examination had then shown a large vessel at the internal os, which had probably been closed temporarily by twisting. Before the hemorrhage could be controlled the patient had become pulseless and unconscious. Under saline infusion and other methods of stimulation she had been resuscitated, and was now nearly well.

DR. A. ERNEST GALLANT said that he had seen recently two cases of subperitoneal fibroids in which he had advocated postponing the operation as the growths did not give rise to any symptoms. Many women with fibroids suffered from pressure on the bifurcation of the aorta, as indicated by intense local tenderness in addition to pain. The amount of hemorrhage was determined, not by the size of the tumor, but by its situation, hemorrhage with subperitoneal fibroids being slight as compared with that observed in connection with the submucous variety. The general rule was, that a woman who began to menstruate late in life would cease to menstruate early, and *vice versa*. Observation of cases of fibroids showed that

the fibroids lengthened out the menstrual life, often as much as six years.

Dr. Balleray said that up to a few years ago he had been ultra-conservative in his work, and on that account had seen many cases in which the fibroids had atrophied after the menopause. He felt sure that he must have seen as many as fifty or sixty such cases. He had seen two or three in which death had resulted from suppurative disease of the kidney as a result of pressure on the renal vessels. He believed in operating on these now, if the tumor was growing rapidly, or if there were severe pressure symptoms or much hemorrhage, and also if there had been an attack of acute peritonitis.

Dr. Louis J. Ladinski presented a specimen of fibroma that had been removed from a woman forty-six years old, who although married eighteen years had never been pregnant. When seen a few months ago she had stated that she had noticed an increase in the size of her abdomen for the past eight months, and that this had been associated with such severe pain that her health had greatly deteriorated. The tumor had been removed by abdominal section according to the method of Kelly, viz., tying off the vessels and cutting down on the broad ligament. A ligature was then placed around the ovarian artery, and then the broad ligament was cut down until the uterine artery was exposed, when it was tied. By this method the tumor had been removed in the present instance without the slightest difficulty, and with almost no hemorrhage.

**Cyst with Twisted Pedicle Simulating Ectopic Pregnancy.**—Dr. Ladinski also presented a specimen of cyst with a twisted pedicle. The case had closely simulated extra-uterine pregnancy. The patient at the age of thirty-six years had been admitted to the Beth Israel Hospital on March 23, 1899. She had had ten children. About one week previous to admission she had been suddenly seized with severe pain in the left iliac region, followed by attacks of faintness. These fainting spells had recurred the following day. Examination had revealed an enlarged uterus, but there were no hemorrhages from this organ. About four days later there had been evidence of internal hemorrhage, and the tumor had increased in size. On opening the abdomen free blood had been found in the general peritoneal cavity, and a dark gangrenous cyst. The pedicle showed four complete twists, and at one portion a spontaneous partial amputation. From this point the hemorrhage had taken place.

Dr. Balleray referred to a case of twisted pedicle occurring in a woman three months pregnant. She had suddenly collapsed one day, and on the day following there had been a slight discharge of blood from the vagina. This had been repeated two or three days later. Examination had revealed a rather large mass in the pelvis, and this could be displaced slightly from the uterus. The abdomen had been opened the following day, and the diagnosis of pregnancy complicated by a cyst with a twisted pedicle had been confirmed.

**The Differential Diagnosis.**—Dr. Wells said that an ovarian cyst with a twisted pedicle was not very rare, and the differential diagnosis from ectopic pregnancy was important. The pain and the collapse were somewhat different from those found in ectopic pregnancy, the pulse rate not being so much increased. In a few days there would usually be some evidence of peritoneal irritation. In ectopic gestation it was very rare for the pregnancy to last more than two or three months, so that the history was a valuable aid. Ovarian cysts with twisted pedicles were usually decidedly larger than the average ectopic gestation.

Dr. Gallant presented a simple multilocular ovarian cyst removed from a woman, sixty-four years of age, by operation on March 1, 1899. The case had pursued a normal course up to the ninth day, at which time the temperature had suddenly risen to 102° F. without obvious cause. After two days the temperature had fallen, and then she had begun to secrete an excessive quantity of pale urine. The patient had then made an excellent recovery, but he had been puzzled to explain the polyuria. By actual measure four gallons of urine of low specific gravity had been voided daily.

Dr. Brown, of Montclair, was inclined to attribute it to nervous influence, and the rise of temperature to some slight indisposition such as a tonsillitis. A few years ago, he said, a patient some days after confinement had had an exceedingly severe convulsion in which she had bitten her tongue. She had then begun passing two gallons of urine daily, and had kept this up for some time. Microscopical examination had revealed a few hyaline casts, and the urine had been of low specific gravity. Dr. Janeway had seen the case in consultation, and had expressed the opinion that this large quantity of urine had been secreted as a result of a fright about herself. Since then the patient had been entirely well, and he had never seen any other evidence of hysteria about her.

Dr. Gallant said that the excessive flow of urine in his case had continued for four days, and had then gradually declined.

**A Portable Operating-Table.**—Dr. Brown, of Montclair, presented a portable operating-table, for which he claimed no originality except for the special method of constructing the hinge connecting the table with its stand. The table complete weighed less than thirty pounds, and could be made for $10. It could be folded up to a convenient size and transported in a canvas case. It was made of wood varnished with shellac.

Dr. Ill said that for several years past he had used, with much satisfaction, an outer and an inner frame which could be adapted to any ordinary table and used in conjunction with a Kelly pad and an Edebohls support.

Dr. Gallant thought it was an advantage to have the part of the table on which the shoulders of the patient rested remain level while the rest could be tilted. This arrangement gave excellent relaxation, and allowed of a shorter incision.

---

**The Dread of Death.**—Among the cultivated men and women of the later Roman empire, suicide became a sort of moral epidemic. The fashionable Stoic doctrines, acting on a race which had begun to degenerate and decline and lose its grip on life, killed the dread of death. Men left the world for a whim, "only on the thought to do the same thing over and over again." The Christian doctrine that self-slaughter is a sin did not affect them, and the notion that there was something base in quitting one's post was not yet born. Dryden, in one of his dramas, contrasts finely the feeling about suicide of the ancient and modern world. The Romans, he says, might "discharge their souls" and give them leave to enter the other world. But we, like sentries, are compelled to stand "'neath starless skies and wait the appointed hour." Dr. Goodhart, speaking of the dread of death, says: "I am never tired of saying, because I am sure it is as true as it is comforting, although in opposition to the general belief, that death has no terrors for the sick man. To the living and healthy man it is quite otherwise, but the sick man upon whom death lays his hand pales gently and imperceptibly out of life."—*London Spectator.*

## OUR LONDON LETTER.

(From our Special Correspondent.)

HOSPITAL SUNDAY—ROYAL INSTITUTION—BIRTHDAY HONORS—CLINICAL SOCIETY—GENERAL MEDICAL COUNCIL—SIR G. PILKINGTON, M.P.—NATIONAL HOSPITAL—THE F.R.S.—SIR F. LAKING—DEATH OF DR. SINCLAIR COGHILL.

LONDON, June 9, 1899.

HOSPITAL Sunday this year is fixed for the 11th, and here we are already at the 9th! The Lord Mayor's appeal has gone forth, *The Lancet's* annual supplement was issued with the last number, and if Sunday produces £50,000, that will make up a million sterling collected since the fund was started in 1873. Toward this sum one gentleman, Mr. George Herring, has already promised £10,000. The electrophone company will fit up instruments to enable the patients in some of the chief hospitals to hear the services in the churches on Sunday.

The Royal Institution has just reached its centenary, and a banquet in celebration of the event was held on Monday. The Prince of Wales and a number of distinguished persons were present. The institution was founded by Count Rumford and has been the scene of Sir Humphry Davy's and Faraday's work, and more recently Professor Tyndall's, Lord Rayleigh's, and Professor Dewar's.

The Prince spoke of his early acquaintance with the institution, and told how his father sent him and his brother nearly fifty years ago to Faraday's Christmas lectures. "I have not forgotten," said he, "the interest we took in these lectures, nor the clear way in which the great professor explained to boys the scientific problems of the moment, nor the beautiful way in which he demonstrated the chemical experiments which were the order of the day." The celebration was continued on Tuesday at a commemoration lecture delivered in the institution by Lord Rayleigh, at which the Prince presided. Finding it impossible to give even a brief account of the famous scientific men who have been connected with the institution, the lecturer described some of the achievements of Thomas Young, a man whose genius he said "was not fully appreciated in his own generation and is even yet hardly fully appreciated." After the lecture twenty-six famous men of science were presented with the diploma of honorary member, among whom was Professor Ames, of Baltimore, U. S. A. Most of the European countries were represented among the recipients. The company then examined the collection of apparatus and the Davy and Faraday memorials.

In the evening the Lord Mayor gave a reception at the Mansion House in honor of this centenary.

The list of honors conferred on the Queen's birthday was more meagre than rumor had led us to expect, so there is much disappointment in various circles. Medicine has not been overlooked. There is a baronetcy for Burdon Sanderson and a K.C.B., for Michael Foster, so physiology takes the medical chief share. But Mitchell Banks gets a K.C.B., so surgery also scores. The same distinction is given to Dr. J. Sibbald, who is a commissioner in lunacy, and to other officials. Surgeon-General A. A. Gore received a C.B., Major Baptie a C.M.G., and Lt.-Col. W. G. King a C.I.E.

At the annual meeting of the Clinical Society the report showed the finances to be in a satisfactory state and the attendance of members during the year to have been very large. The usual votes of thanks were heartily passed to the retiring officers, and the council's list of their successors was elected. Sir R. Douglas Powell is the president for the ensuing year.

M. Betham Robinson described a case of acute intestinal obstruction caused by adherent appendix forming a band associated with fœtal arrangement of the peritoneum, in a girl aged seven years. She died soon after an operation. At the post-mortem not only were the ascending colon and cæcum freely movable, but the third part of the duodenum had a mesentery. There was no sign of the appendix having ever been inflamed.

Mr. Herbert Allingham showed a case of subclavian aneurism which he had ligatured in the first portion, and had removed thirty-eight days afterward. The whole length of the clavicle had to be exposed and the greater part removed. The patient rapidly recovered and can use his arm with comfort. Section of the aneurism showed that its cavity was largely occupied by a firm clot. The blood passed into it from the subclavian and out posteriorly by what appeared to be the profunda cervicis.

The General Medical Council continued its sittings until yesterday. Thursday and Friday were devoted to its judicial work, Saturday to dental matters, and this week to a number of important subjects.

The curious case of McKay, who was charged with perjury by the coroner, before whom he swore he had made a post-mortem, while it was shown that his examination had been incomplete, in fact a mere pretence, ended in his expulsion from the register. Dr. Stewart, a medical officer to a dispensary where the unqualified dispenser was alleged to have assisted him, got off a little easier, but was ordered to come up for further consideration at the next session. The name of S. B. Shekleton, who was accused of aiding and abetting Rowland in getting registered under the name of Nugent, was ordered to be removed from the register.

The propriety of recognizing grammar schools as places of study for some of the subjects of the first year of the curriculum was warmly debated. The English conjoint board was accused of an attempt to whittle down the requirement of the extra year. The representatives of the two royal colleges protested vigorously, and it was even said the conjoint board might insist on their students not registering with the council. The threat was unheeded, so it is useless to speculate whether in such case students would consent to run the risk of being refused admission to the practitioners' register when qualified.

The Dublin Apothecaries' Hall seems to have cost the council more than £300 for the inspection of its examination of about a dozen candidates, and came in for some sharp criticism. It was of course hotly defended, and we are likely to hear some further outcries as to its rights and the wrongs of Ireland.

Medical-aid associations came before the council, and a resolution was passed expressing disapproval of practitioners being connected with those associations in which touting and advertising for patients are practised.

A committee was appointed to draw up a scheme for preventing personation on the register.

There was a long discussion about the midwives bill, but as that measure has little chance of passing parliament this year it will probably not interest your readers.

Sir George Pilkington, the new M.P. for Southport, is a member of the profession, although long out of practice.

Four members of the profession have attained the coveted distinction of F.R.S., viz., Major D. Bruce, Drs. H. Head, Starling, and Windle.

The annual dinner of the National Hospital for the Paralyzed and Epileptic, on the 31st ult., resulted in a collection of £3,000.

Dr. Sinclair Coghill died suddenly on Monday. He returned home from the Berlin congress on tuberculosis only on the previous Friday. He was best known for his work at the Ventnor Consumption Hospital, but he had before that filled a number of important offices with great credit. He was in his fifty-sixth year. He took his degree at Edinburgh in 1857.

## AIR INFLATION OF THE BLADDER.

LETTER TO DR. BRANSFORD LEWIS ON INFLATING THE BLADDER WITH AIR PRELIMINARY TO THE BOTTINI OPERATION; BY DR. ALBERT FREUDENBERG, OF BERLIN.

BERLIN, GERMANY, May 8, 1899.

MY DEAR DOCTOR: Many thanks for your very interesting paper on "The Question of Inflating the Bladder with Air Preliminary to the Bottini Operation" (MEDICAL RECORD, March 25, 1899).

In January, 1898, directly after meeting with that unfortunate result after operating on an empty bladder, mentioned in your paper, I grasped the idea of inflating the bladder with air for the Bottini operation and discussed it with my assistants; but in consideration of the well-known experiments of Lewin and Goldschmidt, which you also mention, I lacked the courage to carry the idea into effect.

I have operated since then on a considerable number of cases, by filling the bladder with boric-acid solution, and the good results as well as the discharge of large pieces of eschar after the operation proved to me that one undoubtedly gains the desired caustic effects by it. When thus operating I, of course, used a stronger glow-intensity and operated with the blade almost white-hot. Any greater painfulness during these operations I did not notice; and I believe that observations to this effect are only casual. I at least have very often observed that, of two Bottini operations on the same patient, one has been more painful than the other, but cannot with any certainty account for it.

Although I have been much pleased with the results of my operations on a moderately filled bladder—which I mentioned in my paper read before the Deutsche medicinische Gesellschaft von New York, on May 2, 1898—I have been still better pleased when, by your favor of January, 1899, I received the reprint of your article in the *Philadelphia Medical Journal*, December 10, 1898, and thereby learned that you had not only conceived the idea of filling the bladder with air in the Bottini operation—quite independent of my own—but had even carried it out, for the first time, in one patient; on which accept my hearty congratulations!

The better is always the foe of the good.

After that I operated on my very next patient (on February 7, 1899) with an air-inflated bladder, and have since then operated eight times in the same manner; so that up to now I record nine cases of operations on air-inflated bladders (altogether I have operated fifty-eight times on forty-five patients).

As far as these figures allow of a judgment, I consider the air-filling of the bladder a further progress in the technique of the Bottini operation. I have never experienced anything unfavorable in connection with it, and I shall, if later experiences do not change my judgment, most likely continue to operate so.

I may here remark that I fill the bladder with air filtered through cotton, by which process the air is rendered free of bacteria. For this purpose I constructed a little apparatus consisting of a glass tube, conical at one end, with a small piece of rubber tubing attached to the other end. The glass tube is filled, to about three-fourths of its length, with cotton. The rubber tube is joined to the syringe filled with air, while the conical end is joined by rubber tubing to the catheter; so that the air in the syringe is pressed directly through the cotton filter into the bladder. The little apparatus, as well as the catheter, has to be sterilized by steam.

Yours truly,

DR. ALBERT FREUDENBERG.

## "ERUPTIONS OF THE FACE DUE TO NASAL PRESSURE."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of May 6th I noticed a letter from Dr. Carl Seiler, of Scranton, Pa., in which he takes exception and claims priority to my article on "Eruptions of the Face Due to Nasal Pressure," published in the MEDICAL RECORD for March 25, 1899. Dr. Seiler says: "I merely want to point out that it is an error to attribute the facial eruptions to reflex only, as I have shown in a paper covering the whole subject, read before the Philadelphia County Medical Society, October 12, 1887, published in the Philadelphia *Medical Times*, prior to the publication of any others." It is quite evident that the doctor did not read my article carefully, or he would never have made his first objection, "that it is an error to attribute the facial eruptions to reflex only"; nor would he claim priority had he read his own paper of October 12, 1887, recently. This is a paper on "Chronic Rhinitis," and there is no mention in it of nasal pressure.

G. D. MURRAY, M.D.

SCRANTON, PA., June 12, 1899.

## COUNT OF BLOOD CELLS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In counting blood cells it will be found better to count ten or fifteen fields of sixteen squares each, for this reason: Should we count ten fields, we only have to divide the sum of their contents by two, after adding four ciphers; when we count fifteen fields we divide by three instead of two. The reason for this is simple, as we see by referring to the formula: "Find the contents of one square and multiply it by eight hundred thousand to get the contents of a cubic centimetre, as it takes eight hundred thousand of the Zeiss-Thoma counting-chamber squares to make one cubic centimetre." If we count five fields and add four ciphers, we have the desired result, as is easily seen; to divide by five would give us the contents of one field, and after further dividing by sixteen we would have the contents of one square, which, multiplied by eight hundred thousand, would give the contents of one cubic centimetre. Now, if we omit dividing by sixteen, and multiply by fifty thousand instead of eight hundred thousand the result will be the same; and further, instead of dividing by five we multiply by ten thousand, we yet obtain the same result—and multiplying by ten thousand is only the addition of four ciphers. Hence, we see if we count ten fields, we divide by two; and fifteen fields, we divide by three. We are considering dilution 1 to 200; but the idea is adaptable to any dilution for either red or white corpuscles. The amount of time thus saved is certainly an item to be considered.

## HEATED ETHER VAPOR—ITS EFFECTS.

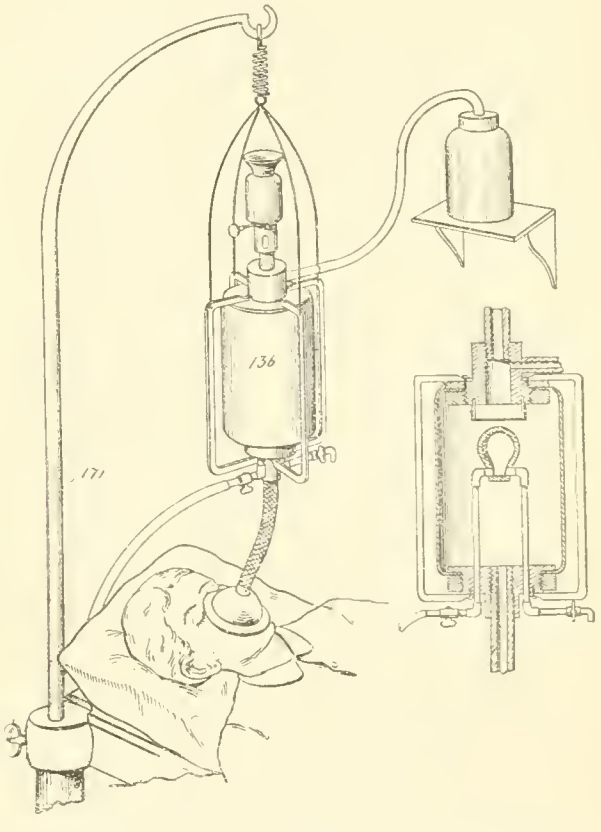
By JOHN S. PYLE, M.D., LL.B.,

TOLEDO, OHIO.

For more than a year past I have been devoting a great deal of my spare time to the construction and improvement of an apparatus by means of which it would be convenient to administer a pure ether vapor, warmed and so attenuated as to do away with many of the unpleasant effects so commonly observed in ether anæsthesia. I have been convinced for some time that most of the disagreeable symptoms arising from the administration of ether were produced wholly by local irritation affecting the nerve endings situated along the respiratory tract. Viewing it in this light, I was led to think of some way to reduce the irritating properties of the compound, without in any way lessening its anæsthetic value. This I have satisfied myself can be done, with the unexpected result of enhancing its anæsthetic value by shortening the required time for producing anæsthesia. Heat alone, supplied to the ether vapor, appears to be sufficient to bring about the desired change; but the addition of an ample supply of oxygen would, in my opinion, make an ideal anæsthetic mixture. My experiments have been made with and without oxygen. I like the additional use of oxygen, as it seems to add to the tranquillity of the nervous system and produce a most natural sleep.

This alteration in the properties of ether, after being subjected to a warming process, is due, in my opinion, to a more perfect evaporation attended with a corresponding attenuation, which accounts for its greater absorbability and increased rapidity of action. The supply of artificial heat, to compensate for the loss upon evaporation, removes the evil effect of cold resulting from the inhalation of imperfectly evaporated ether. I believe that all the disagreeable phenomena witnessed in giving ether are the direct consequence of imperfect evaporation. Ether, like water, will be influenced by varying temperature; the greater the heat, the greater the evaporation. The moisture present in the expired vapor is condensed when discharged in a colder medium, and this being reinhaled carries in particles of ether, which, coming in contact with the delicate respiratory surfaces, causes the irritation and unpleasant effects so commonly experienced. Now if the ether chamber, from which the vapor is removed in inhalation, is kept at a temperature above that of the body, nothing of this kind will ensue.

I introduce here illustrations showing the mechanical device that I have had constructed for the purpose alluded to. The accompanying figures show a sectional view and the apparatus when in use. The illustrations do not do justice to my improved ether inhaler, but will serve the purpose of representing, in the main, the principles involved. As shown in the sectional view, the parts will be seen to consist of a rubber sac (numbered 136), and a heating-bulb having attached thereto two metallic tubes for the purpose of admitting steam and emptying the bulb of any air or condensed water that may accumulate therein. The flexible sac is necessary for the easy exchange of ether vapor; and rubber is of especial value on account of its impermeability and poor quality of conducting heat. The heating-bulb and the tubes inside the rubber sac I wrap with several layers of loose gauze to prevent the action of the heat directly upon the rubber, and for the purpose of absorbing any fluid ether that may reach this point before evaporation. Inside the sac and just above the bulb a layer of gauze guards the upper opening where the liquid ether is admitted and evaporated. The cup on the top of the sac, shown in the accompanying illustration, contains the liquid ether, which is allowed to enter the sac through a very small needle valve. A glass gauge, just under the valve, permits one to see the dropping of the ether, which, by means of the valve, can be regulated by timing the drops so that one, by knowing the exact quantity of ether in the cup, can tell the precise time when it will be exhausted. The cup, in my improved inhaler, has a capacity of six ounces of liquid ether, and will keep a patient under influence for a period of two hours. The rubber tube attached to the metallic tube leading to the bulb is for the purpose of conveying steam from any source of supply. The jar on the bracket is intended to represent the oxygen supply, but I desire it to be understood that this may be taken from any oxygen reservoir and may be admitted through the lower end of the inhaler and be conveyed to the



interior of the sac by means of a tube provided for that purpose. No. 171 in the figure shows a means of attaching the apparatus for convenience to an operating-table. This places the inhaler just over the patient's face, and is easy of management. I have recently made an inhaler in which I use the electric current to supply the necessary heat. In every other way the apparatus is the same.

My experience demonstrates that when ether is heated, from whatever source, the vapor is rendered much less irritating and is unobjectionable as an anæsthetic; furthermore, that vomiting rarely occurs and patients recover from the anæsthesia without any nausea, and express themselves as not feeling the slightest ill effects. The amount of ether consumed will be found much less than ordinarily. It should be remembered that the degree of heat supplied must be sufficient to raise the temperature of the vapor above that of the body.

2123 Ashland Avenue, April 21, 1899.

The Empress of Russia has been delivered of a daughter. A son would have been more welcome.

# Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 24, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 165 | 145 |
| Typhoid fever | 19 | 5 |
| Scarlet fever | 13 | 14 |
| Measles | 33 | 12 |
| Diphtheria | 16 | 30 |
| Laryngeal diphtheria (croup) | 7 | 3 |
| Cerebro-spinal meningitis | 0 | 1 |
| Chicken-pox | 2 | 0 |
| Smallpox | - | 2 |

**Hard Service.**—An ex-postmistress out West is said to be suing the Government for a pension for having ruined her eyesight reading the postal cards which passed through her hands.

**Do They Ever?**—In a public institution of this city there is hung upon the wall of a clinic room the following notice: "Assistants, visitors, and others are requested not to criticise the cases, practice, or personal characteristics of other physicians in this or other cities."

**A Drunken Womanhood.**—There can be no doubt that the great problem before the temperance people of this country is how to arrest the alarming increase of inebriety among women. The lamentable fact that in England woman is especially associated with the sale of intoxicants, that her presence is to be found behind the bars of every drink-shop, has caused the safeguards that surround her in other countries to be set aside, and we stand as a nation in the unenviable position of almost the only one that has a drunken womanhood. The question, therefore, remains for us, not only how to stem the evil, but how we are to deal with those that fall.—Lady Henry Somerset.

**Free Medical Treatment.**—All the free dispensaries and hospitals and similar institutions do not accomplish what they might; do not do half as much good as they were intended to do, because, in the first place, people fear and distrust them, and, in the second place, because they are obnoxious to any self-respecting poor man as being all more or less charitable institutions. Charity?—People do not want charity, those benefiting by it seldom deserving it, and those who do deserve and need it being too proud to accept it, preferring rather to suffer sickness and misery than submit to the humiliation that cannot be disconnected from any kind of charity, no matter how well meant it is.—F. C. Theo. Krüger.

**Proposed Monument to Sir Thomas Browne.**—Subscriptions are being solicited to erect a monument in memory of Sir Thomas Browne, late of Norwich, England, author of the well-known "Religio Medici." The London *Times*, in a leading article, warmly approves the project, and in discussing the paucity of medical men who have gained fame as writers outside their own peculiar province, it speaks as follows: "In the long list of men devoted to the healing art, there is a dearth of those who have shown the highest literary faculties united with the learning of their art and time. Striking exceptions will occur to every one, but Sir Thomas Browne stands by himself, fully versed in the professional learning of his generation, ardently interested in the advancement of his profession, and in every page of his writings making it evident that he is the physician and experimentalist. It would not be a gain if any clever doctor of to-day were to try to imitate the mannerisms of Browne. What he did well was done once for all. But science would not suffer and humanity would gain if accomplished, gifted physicians of our time occasionally sought after his manner to take the large views of their art, its relations to all that is best in the spiritual world, in which Browne delighted. To the physican honest to his calling, and worthy, come naturally, whether he has thoughts of literature or not, ideas which if presented faithfully, and not obsequiously in the train of some theory, would add to that store of moral truths to which humanity turns in its troubles and perplexities. So many persons tell the world more than they really do know. From our profession, brought into close contact with the misery and pathos, the tragedy and irony of life, we do not get all the interest which we strongly suspect the best members of the profession have to give, the practical wisdom and the philosophy of life which come to the best physician, but which are not taught in their technical treatises or Harveian orations. A Religio Medici, a true product of our time, would be interesting."

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ending June 24, 1899:

Smallpox—United States.

### REPORT OF A CASE OF ALCOHOLIC MULTIPLE NEURITIS, WITH AUTOPSY.

BY J. H. LARKIN, M.D.,

ASSISTANT IN PATHOLOGY, COLUMBIA UNIVERSITY,

AND

SMITH ELY JELLIFFE, M.D., PH.D.,

CLINICAL ASSISTANT IN DEPARTMENT OF NERVOUS DISEASES, COLUMBIA UNIVERSITY.[1]

ALCOHOLIC neuritis has been the subject of so many studies that it might appear unnecessary to try to contribute anything new either to its clinical picture or its underlying pathological conditions. Leyden, Erb, Strümpell, Gudden, and others have so thoroughly covered the ground from the clinical standpoint that little can be added to their extensive studies, but in the sphere of pathology newer methods of investigation have offered an opportunity for the recording of certain cytological changes, as yet not thoroughly understood nor classified. While it is perfectly true that of late years a number of observations have been made by means of these methods, the amount of evidence, we believe, is still insufficient to permit of generalizations that might cover all cases of alcoholic neuritis. Heilbronner[2] has in recent studies exhaustively covered the field of the fibre degenerations of the peripheral nerves and of the spinal cord, and it has been the object of the present communication to confine itself to a study of the ganglionic changes observed. Such ganglionic changes have been recorded for years. Their extreme grade in some cases made their recognition comparatively easy, even when studied by the carmine or hæmatoxylin micro-chemical reactions, but their clearer analysis has obtained only since Nissl introduced his general methods. By these methods the changes have been studied by a number of observers experimentally, and in the human subject. Polyneuritis due to other closely related toxic agents —tuberculosis, diphtheria, malaria, typhoid fever, beri-beri, etc., has also been carefully investigated, and the analogies to alcoholic neuritis are close.

The following case has been reported, since it presents certain features worthy of note. It is a simple, uncomplicated case, and the pathological picture, in so far as the clinical history could determine, should show the effects of a sudden acute alcoholic poisoning. Other factors which are known to be the cause of changes in the ganglion cells of the central nervous system can be excluded. This is a condition which is extremely rare among the cases reported which have come to autopsy. In the great majority of these, chronicity, accompanying renal disease, bacterial toxæmias, hyperpyrexia, or other cause of cell degenerations have been present, as revealed by a close scrutiny of the clinical histories. The work of examining these histories has been materially lessened in Gudden's tabulation of forty-eight cases and Heilbronner's careful digest of some sixty cases. No collection of the recent work on alcoholic paralysis, as revealed by the Nissl method, has as yet been attempted. Ewing[1] has given perhaps the best short *résumé*.

History of patient: Mrs. C. S——, aged thirty-five years, admitted to St. Francis' Hospital, May 13th, suffering from paralysis of both arms and legs, with slight catarrhal jaundice, gastric disturbance, and excruciating pain in arms and legs.

Past history: She has been married eight years, and has had five children, two abortions. The oldest child is seven years, the youngest one year old. All the children were normal births and are at present healthy. The patient has had the ordinary diseases of childhood, and has always been a robust and healthy woman. She has always been in the habit of using beer and wine to a moderate extent.

Present history: About one year ago she lost her mother and two brothers under peculiar circumstances. These she considers the causes of her over-indulgence in strong alcoholic drinks. Her debauches were of a periodical nature. She would drink for weeks at a time, taking no food of any account while on these sprees. At the end she would gradually "taper off" and remain well, drinking no liquor in the interval. The periods between these debauches would be months. At one time she went four months without tasting liquor of any kind. Her last debauch began on March 15th (?), 1898. From that time until April 15th (two to four weeks) she drank very heavily. About April 2, 1898, she awoke one morning with a sensation of "pins and needles" in both hands and feet. This continued during the day and for about twelve days, when the sensation changed gradually to pain, slight at first, but increasing as the days went by. She was treated at home this time for rheumatic pains and sciatica. About April 15th she noticed that her skin was turning yellow and that her feet began to swell, and she became somewhat short of breath. The pains in both feet were then of a severe shooting character, while those in her hands were only moderate in degree. From this time on she was evidently growing rapidly worse, and on the advice of her physician was removed to the hospital on May 13, 1898.

On admission: The patient is well nourished. There is some œdema about the face and puffiness under the eyes. There is moderate jaundice, especially noticeable in the sclerotic of the eye. There is œdema of both extremities, with spasmodic twitching of the leg muscles. The patient's facies is one of suffering, and she complains bitterly of the pain in her arms and legs, which gives her no rest.

Physical examination: The heart apex is in the sixth interspace. The impulse is forcible, with some slight pulsation over the pericardium. The heart area of percussion is large. There is a systolic murmur of moderate intensity heard at the apex and transmitted to the left under the axilla, and heard only feebly at the back, at the spine, or the scapula. The lungs are

[1] The writers desire here to express their thanks to Dr. O. Seibert for the privilege of reporting this case, and to Dr. T. M. Prudden for assistance and counsel.

[2] Monatsschrift f. Neurologie u. Psychiatrie, 3, 1898, p. 457 et seq.

[1] Archives of Neurology and Psycho-Pathology, 1, 1898, p. 263.

normal. The liver extends three finger-widths below the free border of the ribs on the right side; its edge is moderately rounded. The spleen is not palpable, but on percussion seems moderately increased in size. There is nothing noticeable about the abdomen. The kidneys: The urine is 1.018 specific gravity, acid; albumin, very delicate trace with nitric-acid test; no casts. White and red blood cells are few. There is no sugar. There is some involuntary evacuation of bladder and rectum. The patient's legs are drawn up. There is marked pain, made worse on pressure over the nerve trunks. Double drop-foot and spasmodic twitching of leg muscles are present. No evidence of atrophy of any groups can be made out on account of œdema. The tendon reflexes are lost on both sides. There is flattening of the muscles of the buttocks, with considerable pain all along the spinal column. There is double drop-wrist; the skin and tendon reflexes are abolished. The muscles of the forearm are atrophied and flabby.

The pain sense was examined by electricity, hot and cold water, and by needle. The electrical examinations were not extended. The faradic current alone was used. The current employed was so strong that a normal individual could not stand it, yet the patient never evinced the slightest discomfort. Complete analgesia to needle pricks was present. Tests with heat and cold were not successful, as the statements of the patient were not satisfactory. Reaction of degeneration was well marked in the extensors and flexors of lower limbs and forearms.

The patient continued to grow steadily worse day by day. The pain in the back, arms, and legs was excruciating, and required anodynes for relief. On May 27, 1898, the patient grew slightly delirious. The temperature was 103° F. The pulse was rapid and small. On the following day the delirium was more marked and the patient had to be restrained. On May 29th, the delirium changed to a stuporous condition. In this she remained till she died on May 31, 1898, without any marked rise in temperature.

The autopsy was made by Dr. Larkin, three hours post mortem. The body is that of a well-nourished woman. There is moderate general jaundice; no rigor mortis; no post-mortem lividity. There are several nodular tumors (sebaceous cysts), about the size of a marble, in the subcutaneous tissue of the scalp, freely movable. There is an old cicatrix over the front of the tibia at lower third, the probable seat of recent traumatisms. Both mammary glands are well developed. There is moderate subcutaneous fat tissue, which is bile stained. The muscles are dark brown in color. The abdominal cavity is yet warm. There is about a litre of bile-stained serum in the abdominal cavity. There is no evidence of peritonitis, either old or recent. The liver extends three finger-widths below the free border of ribs.

The lungs: There is no fluid in either pleural cavity. There are no adhesions. The posterior pendent portions of both lungs are in the condition of hypostatic congestion and œdema; otherwise they are normal.

The heart: There is no fluid in the pericardium. There is moderate pericardial fat tissue. The heart weighs 60 gm. There is hypertrophy of the wall of left ventricle. The aortic valves are normal. The mitral valves are thickened along the free edge with thickening of the chordæ tendineæ; the pulmonary and tricuspid valves are normal. There is no atheroma of the aorta. The liver is congested, slightly increased in size and granular, and is in a condition of beginning mild cirrhosis. The spleen is increased in size; its pulp is dark brown; the capsule is thickened and the trabeculæ are prominent. The kidneys weigh 245 gm. They are uniformly congested and succulent, with non-adherent capsules and irregularities in the markings of the cortex, which is also slightly diminished. There are no changes in the blood-vessels. The pancreas presents no gross changes. The stomach is coated with glairy mucus; there is some congestion at the pylorus, otherwise normal. The tubes and ovaries as well as the uterus are normal. The brain and spinal cord present no observable gross anatomical lesions, the pia mater over the frontal lobes alone showing some slight œdema.

Microscopical examination: The lungs, heart, spleen, and pancreas show no microscopic change. The liver shows increase of connective tissue in Glisson's capsule; there is general congestion of central veins and capillaries. The kidneys show chronic congestion with slight increase of connective tissue between tubules; swelling of cells lining Bowman's membrane, increase of cells in and on capillary tufts; no degeneration of the epithelium lining tubule; the blood-vessels except for congestion are normal. Posterior tibial nerve: the sections show slight œdema of connective tissue and swelling of the endothelium lining the blood-vessels.

Technics: The brain and spinal cord were removed and placed in absolute alcohol within three hours of the time of the patient's death. The pia of the brain was removed and the cord was cut in sections of about 2 cm., still adhering to the dura on one side in order to *orientier* the segments. Portions of the peripheral nerves were fixed in absolute alcohol and in osmic acid.

The microscopical technic need only be summarized. After thorough fixation and hardening several weeks, portions of the spinal cord and brain were embedded in celloidin, and sections cut from 5 to 20μ in thickness. These were stained by Nissl's methylene-blue preparation and mounted in damar. Held's modification without the acetone was also employed. Delafield's hæmatoxylin and eosin were employed in some of the studies of the nucleus and for the blood-vessels. Heidenhain's iron hæmatoxylin was also employed in some instances. Von Rehm's method gave excellent pictures of neuroglia elements. The cord was studied at intervals of 1 cm. throughout its entire length. The medulla and pontine regions were also sectioned through the more important cranial nerve nuclei. Sections from the cortex were taken from a number of areas; these will be discussed under the head of the cortical findings.

Spinal-cord changes: The white matter of the spinal cord was not closely investigated. The studies of the fibre tracts by Gudden, Heilbronner, and scores of others have demonstrated very clearly the great alterations that may be found in alcoholic multiple neuritis. Degenerations are extremely common in the ascending columns, notably those of Goll and Burdach, and the relations of the process found in alcoholic neuritis to the degenerations found in tabes have been exhaustively treated by these authors.

The examination in the present instance was purposely confined to the study of the ganglion cells, and in these there was found a degeneration of very marked extent. In many of the contributions on the subject of the ganglionic changes in this affection it is apparent that a large number of the cases are not simple ones of pure alcoholic neuritis, but are instances of the occurrence of a neuritic invasion in people who have been suffering perhaps for years with some form of constitutional or exogenous toxæmia. In many of the cases examined by the newer methods the element of chronicity is also to be borne in mind, and in still others hyperpyrexia may add its complicating changes. These points of difference are taken to be of importance in the description of the lesions of this case, since it presents a clear picture of an acute lethal intoxication in a healthy adult, and therefore more closely approxi-

mates the experimental standards than most cases recently reported and studied by the newer methods.

Description of the lesions in the cord: From the level of the upper cervical cord to the conus marked ganglionic degeneration was the rule. This involved not only the ganglion cells of the anterior horns, but also those in the posterior horns and throughout the dorsal cord, the columns of Clarke, and in the lumbo-sacral enlargement the nucleus of Stilling. The different levels may be considered seriatim. Manipulative artefacts were found in the cervical cord, which, to a certain extent, confused the picture, yet the ganglion cells throughout this region could be seen to be in various stages of chromatolysis. A careful count of the ganglion cells in the various levels from the seventh or eighth cervical downward is here appended, with the number of normal or approximately normal cells found therein. From the first or second to the seventh or eighth cervical there were on the average about ten per cent. normal cells in the anterior horns; fully ninety per cent. were degenerated.

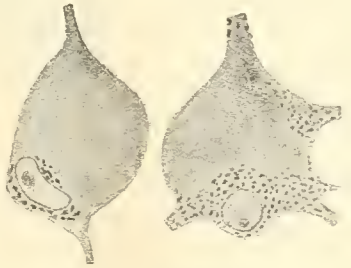
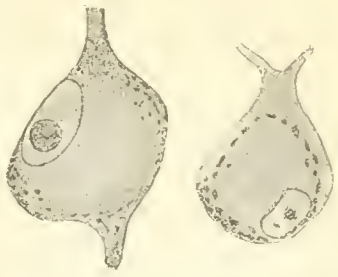
The above table indicates the extent of the cellular degeneration. As to its character the following general remarks may be made: Nearly every described grade of chromatolysis was observed—peripheral, central, perinuclear, etc.—but the predominant type was the well-known central chromatolysis so characteristic of axonal degenerations. In a great many of the cells, perhaps fifty per cent. of them, from the fourth to the tenth dorsal region and in the lumbar enlargement, the chromatolysis had advanced to the extreme grade of complete loss of stainable substance, reticular or cytoplasmic, and even to complete cell destruction. Eccentricity of the nucleus was a predominant factor; for the plane of the section, it was present in at least thirty per cent. of the cells; sections cut in different planes would probably show it to be more universal.



FIGS. 3 AND 4.—Degenerative Change in Upper Dorsal Region. Third segment, left side; central and peripheral chromatolysis, nuclear eccentricity and chromophilia

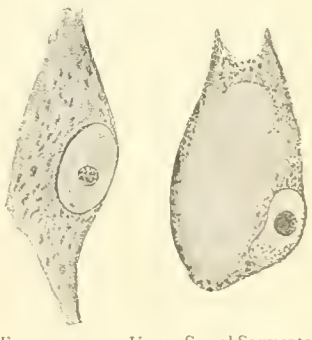
No relationship between the eccentric position of the nucleus and the principal dendrites or axis-cylinder process could be shown because of the practical impossibility of seeing the cell and all its parts, even in a series of sections. As far as could be ascertained, the nucleus appeared to be at the farther extremity of the cell, as contrasted with the site of origin of the axis-cylinder process, but this is more a matter of conjecture than proof.



FIGS. 5 AND 6.—From Columns of Clarke. Upper dorsal segments, left side, showing different chromatolytic changes.

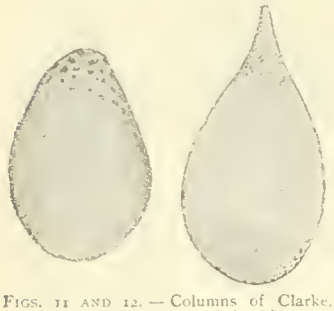
The greater involvement of the cells of the left side of the cord is noteworthy, the decrease in their number signifying actual cell destruction, and in those remaining the chromatolysis was more extensive. Changes in the cyto-reticulum of the nucleus were manifest in most of the levels, though this part of the cell structure seemed more resistant than the structures of the cytoplasm. No special constant nucleolar variations could be posited; fragmentation occurred, but seemed capricious, occurring in fairly normal cells and in cells completely destroyed; well-marked nucleoli were abundant in badly degenerated cells. The absence of nuclei was probable in a number of cells, this did not occur so often as would appear from a study of any one plane, since the section just above or just below might contain the nucleus. This consideration leads the writers to maintain that for the general study of the degenerate processes in nerve cells it is wiser to use sections which are cut thicker than is frequently advised. Ganglion cells are frequently from 60–90μ in diameter, and sections of 5–10μ, which are said to be desirable, do not permit a correct interpretation of the structure unless cut in series and so studied. We prefer sections about 20μ in thickness for average work. Specially thin sections certainly are of service for the finer cytological detail of the cyto-reticulum, but for the general study of the chromatolytic process we believe them to be less serviceable. This is especially true in the case of the cells of Clarke's columns. In the present case it would appear that there was a marked degeneration of practically the entire column of Clarke, yet the structure of the cells of Clarke's column, we think, is different from those of

FIGS. 7 AND 8.—Degeneration of Anterior Horn Cells, at second lumbar segment, right and left sides. 7, Peripheral chromatolysis, nuclear chromophilia; 8, complete chromatolysis, nucleus disappeared, cyto-reticulum still present (in specimen).



FIGS. 9 AND 10.—Upper Sacral Segments, anterior horns showing milder grades of chromatolysis. Fig. 9 is almost normal save for slight fragmentation of granules and eccentricity of nucleus; Fig. 10 shows slight central chromatolysis.

the anterior horn in several cytological details; and it undoubtedly occurs that in these cells very thin sections give pictures of what appears to be marked central chromatolysis with centric nuclei and a fringe of cross sections of chromophilous bodies on the periphery of the section. Believing as we do that the interior of the body of the cells of the column of Clarke has fewer formed chromophilous bodies than the periphery, it would follow that such a picture is readily misinterpreted. When the granules at the periphery have entirely disappeared and the nucleus is eccentric, the interpretation is beyond cavil, but there are, we believe, grounds for questioning the observations made on too thin sections in the cells of the columns of Clarke.



FIGS. 11 AND 12. — Columns of Clarke. Eighth dorsal segment, left side, complete cellular degeneration.

Portions of the brain were taken from the following areas (their exact location is represented in the subjoined diagram): 1, superior frontal; 2, mid-frontal; 3, inferior frontal, just in front of the pre-Sylvian fissure; 4, operculum, just behind the pre-Sylvian fissure; 5, at the base of the central fissure, anterior central convolution; 6, anterior central convolution about the junction of the middle and lower third; 7, anterior central convolution, junction of middle and upper third; 8, top of anterior central convolution, including part of the paracentral lobule; 9, post-central convolution; 10, middle superior parietal; 11, superior temporal; 12, mid-temporal; 13, inferior temporal; 14, inferior parietal; 15, cerebellum.

These were treated by the same technical methods as outlined for the cord.

1. Superior frontal convolution: The large and medium-sized ganglion cells throughout fairly normal; sub-pycnomorph, pigment prominent; many nuclei eccentric, though in these cells where the nucleus makes such a large part of the cellular mass, little weight is to be placed upon such eccentricity. The blood-vessels were not materially altered.

2. Mid-frontal convolutions: The ganglion cells were normal in this region as far as could be determined, though many had eccentric nuclei.

3. Preopercular convolutions: No appreciable lesions were observed.

4. Operculum: In the large and medium-sized ganglion cells the cytoplasm was finely granular. Pigment was present in many, and in a few of the cells the nucleus was eccentric. The blood-vessels were not affected.

5. Base of the anterior central convolution: The large and medium-sized ganglion cells showed little trace of any stichochrome structure. The cytoplasm was finely granular; many of the nuclei were eccentric.

6. Anterior central convolution, junction of lower and middle third: The medium and large sized ganglion cells were markedly bleached. The typical stichochrome arrangement of the chromophilous bodies was absent, fine granules taking their place. The majority of the nuclei were centric. The dendrites were paler than in the normal condition and showed no stichochromes. Advanced grades of chromatolysis, similar to that found in the cord, was found in a few of the large ganglion cells of this region. The blood-vessels were not markedly altered, though moderately dilated.

7. Anterior central convolution, junction of upper and middle third, was not so markedly affected as the section 6. Stichochrome structures were here apparent and the nuclei were more centric. Many of the cells, however, had nothing but a fine granular cytoplasm. Pigment was rare. The blood-vessels were normal.

8. Top of the anterior central convolution, including a part of the paracentral lobule. Many of the cells in this region showed partial degenerative changes, especially those in the paracentral lobule. Many had eccentric nuclei, and the reticulum of the cytoplasm was obscured. But few of the ganglion cells had retained any stichochrome arrangement of their chromatic substances.

9. Post-central convolution, middle third: The cells in this region were not materially altered.

10. Superior parietal convolution: The medium and large sized ganglion cells of this region were noticeable by reason of a large amount of pigment. Beyond a certain amount of granulation of the cytoplasm they appeared normal. There were no nuclear changes observed.

11. Superior temporal region: There were no marked structural changes in this region. A slight grade of granulation of the cytoplasm alone was observed.

12. Mid-temporal convolution: Few structural modifications were found in this region.

13. Inferior temporal convolution: Mild degenerative changes were found in the sections from this region. The dendrites were not prominent and the cyto-reticulum was obscured. The reticulum of the nucleus was normal.

14. Inferior parietal convolution: This seemed normal.

15. Cerebellum: The Purkinjé cells were pale throughout. In nearly all of them there were some small chromophilous bodies clustered near the nucleus. The dendrites were mostly colorless and the nuclei were in a stage of chromatophobia. There was no marked eccentricity of the nuclei of the Purkinjé cell. The nucleoli were regular. The blood-vessels of the cerebellum seemed normal.

*Résumé* of changes in the cortex: There were, therefore, distinct degenerative lesions irregularly distributed throughout the cortex of the brain. These consisted for the most part of the following: In the cortical stichochrome cells of the motor cortex there was a disappearance of these bodies, an irregularity in the position of the nucleus, and qualitative variations in the staining portions of the cytoplasm. The archyostichochrome cells in many cases had lost the characteristic arrangement of their reticulum, and the cytoplasm showed a distinctly granular structure. Peripheral chromatolysis was present in the Purkinjé cells of the cerebellum.

FIGS. 13 AND 14.—Cells from Nucleus of Stilling. Lumbar and sacral region, showing. 13, complete chromatolysis; 14, beginning perinuclear chromatolysis.

In any discussion of the lesions produced by the alcoholic poison, the *rationale* of the process, in so far as it is understood, should be borne in mind. It would seem that two distinct series of changes might be going on simultaneously in multiple neuritis—one similar to that produced by a degeneration or a cutting-off of the axis-cylinder process, and the other a direct poisoning of the ganglion cell. Under experimental conditions the changes produced by the former process are fairly well understood, but

the cytological variations, which might be due to the direct poisoning, may not be so readily correlated. Vas, Dehio, Berkley, and Stewart have given us contributions to this latter question; with the former ques-

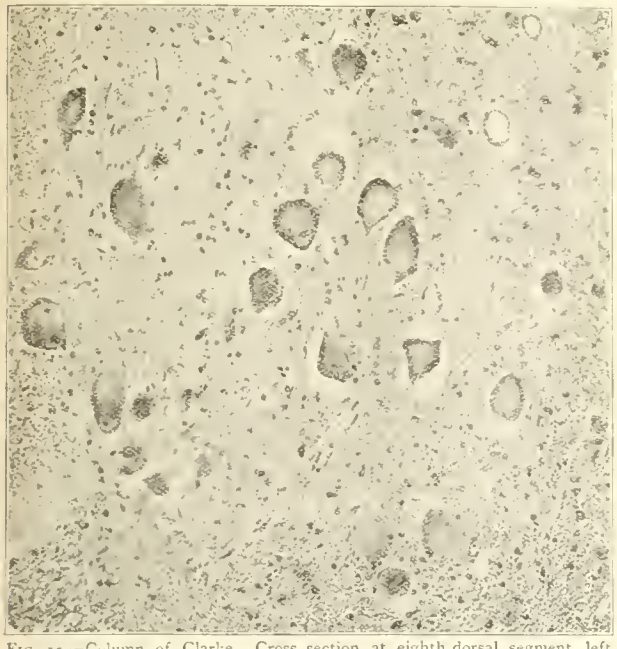


Fig. 15.—Column of Clarke. Cross section at eighth dorsal segment, left side, showing various grades of chromatolysis. (Photomicrograph by Dr. Leeming.)

tion a host of observers have busied themselves. Marinesco has compressed the final matter in a nutshell, thus: "After the section of a motor nerve or of a sensory nerve, in from five to six days there are certain positive lesions in the ganglionic centres of these nerves, as shown by Nissl's method of examination. These, as given in *résumé*, are: (1) A partial dissolution. Disappearance of the chromophilous elements of the nerve cells. This process may affect the entire cell body. The nucleus, more or less altered, is usually found at the periphery of the cell body. (2) When the lesion has affected the entire cytoplasm of the cell, it presents a homogeneous aspect. (3) A process of restoration may take place as the regeneration of the sectioned nerve takes place."

But while this presents a picture of the end results, it tells very little of the natural history of the process, if it has a definite cycle. Ewing believes from a wide experience, in by far the best presentation of the whole subject of ganglionic changes thus far given to technical pathological literature, that the minute variations in the process of the parenchymatous degenerations present an almost endless variety of possibilities. "The minute lesions seem to differ in every case, and the range of minor peculiarities is practically limitless. Especially in the advanced stages of acute and chronic degeneration the aspect of the cells may be so heterogeneous that classification of the lesions is impossible."

The reported cases of fatal alcoholic multiple neuritis, examined by the newer methods, have not been very numerous, nor does there seem to be a consensus of opinion with reference to the central lesions. In this form of neuritis the absence of changes is reported by Tooth, Achard and Soupault, Dejerine, and others. The first two, though coming within the "Nissl epoch," do not appear to have been examined by his methods, but in them attention was paid to the search for central lesions.

In Tooth's[1] case, which clinically ran a typical course, there was extreme degeneration of the peripheral nerves, but no central lesions were found. The cytological investigation was by means of the older methods for the most part.

Achard and Soupault[1] report two cases—one negative and one positive. The first occurred in a man, aged twenty-eight years, first received in the hospital in a condition of acute delirium after a two months' steady indulgence in absinthe. Three weeks previous to entrance he commenced to have the initial paræsthesiæ and pain of the neuritic process. He had been delirious two days previous to his entrance. His delirium cleared up in a few days, and the peripheral-nerve involvement was then manifest. He had marked paralysis of the limbs of the lower extremity, the extensors in particular, with foot-drop and also extensor paralysis of the arms and forearm. The patient developed a high temperature and died of syncope with evening temperature of 39.2° C. (102.5° F.). The autopsy showed meningeal congestion. The cord seemed normal. There was congestion of all of the viscera and heart muscle (myocardial fragmentation). The cells of the anterior horns were normal; some in the cervical region were tumefied and transparent. There were no changes in the medulla. The examination of the nerves showed some degeneration, especially in the median, cubital, and right radial nerves. The changes in the heart, kidney, and liver were of a parenchymatous type.

The case of Dejerine and Thomas is of more interest. These authors[2] report some observations made upon a case of a cook, forty-eight years of age, who had alcoholic paralysis of the lower extremities, with atrophy and talipes equinus. There was hyperæsthesia of the skin and of the muscles, and abolition of the patellar reflexes. On autopsy there were found marked lesions of the cutaneous nerves of the lower extremities. There was integrity of the anterior and posterior roots, gray matter, and ganglion cells. It is of interest to note in this case that the patient was in process of recovery. There had been a complete paralysis of the upper extremities, but this had disappeared and the lower limbs were regaining their power somewhat. The cutaneous nerves were examined in osmic acid, and the cord was examined by both the Nissl

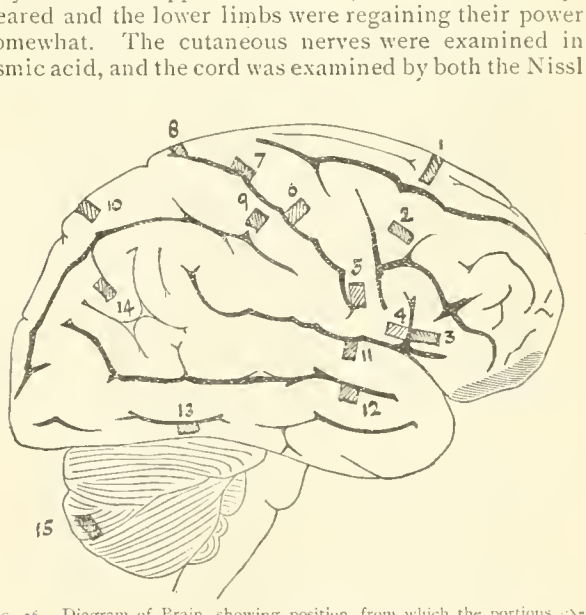

Fig. 16.—Diagram of Brain, showing position from which the portions examined were taken.

and Marchi methods. The authors believe that the absence of the ganglion-cell changes may have been due to the fact that the peripheral nerves were re-es-

tablishing their function, though at the time of death paralysis was still present. Moreover, they show that chromatolysis should not be too rigidly interpreted, since it may be found in cases like these, or in cases, as Jacottet[1] has shown, in which there was apparently

FIG. 17.—Cell from Anterior Horn, fifth cervical segment; central chromatolysis, eccentric nucleus, central destruction of reticulum. (Photomicrograph by Dr. Leaming.)

no impairment of function, yet marked cellular changes were present. Thus chromatolysis links itself with other parenchymatous cell changes, and its significance is great, yet not pathognomonic of any single type of lesion.

Soukhanoff[2] has reported a positive and a negative case. His negative observations were in the case of a young man of twenty-one, who for some years had been a hard drinker. He had a poor family history and suffered from delirium tremens, so that his case might be considered one of multiple alcoholic intoxication, extending over a period of some years. At the autopsy it was shown that he had a marked chronic leptomeningitis; the cerebral substance was œdematous and the ventricles were markedly dilated. There was sclerosis of the arteries of the base of the brain. There was a purulent infection of the pleural sac and tuberculous cavity formation in the right lung. Thus this case is not an uncomplicated one, and the changes in the nervous tissue may be due in part to the alcoholic poison and in part to the action of toxins. The peripheral nerves stained with osmic acid showed the characteristic picture of degeneration. The spinal cord in the lumbar region treated by Marchi's method showed a marked involvement of the posterior columns. There were degenerated fibres interspersed with healthy ones. Some few degenerated fibres were found in the anterior and lateral columns, and in the anterior commissure there were also degenerations. The cervical region showed a most marked degeneration in the column of Goll. Examined by the method of Nissl and by carmine, the author states that notwithstanding the extensive fibre degenerations there were no appreciable lesions noted in the ganglion cells. The changes in the medulla were of the same type. There were a few degenerated fibres going to and from the hypoglossal, facial, abducens, and oculo-motorius nuclei. Examination of the brain was negative by Marchi's method.

From a careful reading of the histories of these cases as reported, the evidence is not sufficient, we believe, to exclude the possibility of there being some cytological alterations. In the less marked cases, as those of Dejerine and Thomas, the absence of grave lesions might be expected from what we now know of repair in ganglion cells, and in the more positive case of Soukhanoff it is not evident that a rigid examination was made throughout the cord, since more attention was paid to the fibre degenerations and only sections here and there were taken for the Nissl technique, a procedure which is only too apt to cause misleading conclusions.

The positive cases are comparatively numerous. We here report a number of them in which lesions similar, in part, to those found by the writers were present. Ballet and Dutil's[1] case is of interest in that it shows most of the lesions observed by us, and yet, so far as these observers were able to determine, no direct toxic agent could be found. These authors report the case of a man, aged forty-four years, who, without any ascertainable infectious or toxic cause, developed at the age of forty-four years all the symptoms of a multiple neuritis. The examination of his peripheral nerves showed the typical lesions of neuritis. There were a number of degenerated fibres in the anterior roots. The posterior roots were healthy. The most marked alterations, however, were found in the cells of the anterior horns. In a number of these there was absence of the chromophilous granules, the cytoplasm had become homogeneous and turgid, and in some of the cells the nuclei had vanished, the cells had become globular, and the prolongations had disappeared. Changes in the nuclei were also evident; the nuclear mass was irregular and even star-shaped in some of the affected cells. The peripheral position of the nuclei was evident in many of the diseased cells. The *resume* of the authors' contribution is as follows:

1. We have been able to show that in a case which presents the clinical picture of an idiopathic polyneuritis, there were lesions of the nerve trunks, of the anterior roots, and marked alterations in the ganglion cells of the anterior horns.

2. When one desires to examine for spinal cell changes in cases similar to this, it is necessary to use other cytological methods of examination than picrocarmine; such as the method of Nissl, or, if the nucleus is to be studied, hæmatoxylin.

3. It does not suffice to affirm that the polyneuritis has been secondary to alterations in the spinal cord, since the poliomyelitis could be secondary to the peripheral nerve lesions.

4. The arguments which are of value in favor of the medullary origin of the polyneuritis are of another kind.

The second case[2] occurred in a woman, twenty-five years of age. She was admitted to the Salpétrière following a slight convulsive attack. She had been drinking for some time, but presented a very irregular history. A month after her admission the symptoms of the neuritis developed and continued up to the time of her death, which occurred three months after the first symptoms. Phthisis was a complicating factor. Microscopical examination of the medulla showed some nuclear degeneration at the region of the olivary nucleus. The spinal cord showed sclerosis of the columns of Goll and of the lateral columns. The cells of the anterior horns were remarkably degenerated. In certain groups the cells were normal; in others, changes were profound. Normal and diseased cells were intermingled in places without any regularity.

[2] Achard and Soupault: *Loc. cit.*

The changes for the most part were of interest only in the variation of contour, loss of prolongations, changes in colorability of the nucleus, and its dislocation to the periphery of the cell. Sometimes there was complete loss of the nucleus. These changes were noted in the cervical, dorsal, and lumbar regions, the cell changes in the dorsal region being extreme. Marked degeneration of the nerves was noted, including that in the pneumogastric.

Marinesco[1] reports a case of polyneuritis with grave central changes, but viewed from our point of view it has little bearing save upon the general peripheral pathological findings in cases of this character. The case was one lasting over two years, in an old rheumatic patient who had early in 1892 paralysis and atrophy of the muscles following an attack of acute articular rheumatism. He died in 1894. The cell lesions were marked.

See *Comptes rendus*, 1896, p. 467, for another case in contradistinction to the case observed by Dejerine and Thomas, with no cytological changes. These same authors published formerly a marked case, illustrating most of the phases of the chromatolytic process.[2] In this case incontestable lesions existed in great numbers in the cells. These lesions were not equally distributed throughout the whole cord. They predominated markedly at the level of the lumbo-sacral enlargement. They diminished in the posterior inferior portion of the cervical enlargement and were hardly appreciable in the upper cervical roots. They showed further a certain parallelism between the cell lesions and the changes of the peripheral nerves. These lesions were essentially polymorphous. Beginning in one stage the cell appeared swollen, often to a considerable degree. Instead of measuring 60μ some reached 85 to 90μ. This increase of the volume was constant in all the portions of the cells, which tended to become more and more spherical; at the same time the protoplasm underwent profound modifications. It took on a general blue tint, often more marked at the middle of the perinuclear zone. The chromatic substance was represented here and there by a few striations. The plaques became finely granular. These diverse cytoplasmic alterations did not appear to them to begin by preference in the region of the nucleus. They did not seem to follow any clearly definable law. In the second stage the volume of the cells diminished; its protoplasmic mass especially staining less and less intensely. The nucleus with its nuclear membrane was made out with difficulty. It underwent a more or less considerable displacement. Finally in the last stage, which is more rarely reached, the cell body, very pale throughout, does not present any protoplasmic prolongations. The chromatic elements are reduced to minute granules scattered here and there. The nucleus is located at the periphery; its substance is feebly tinted; its membrane is often destroyed. These cell lesions having been already described in the more extended works of the pathological histology of alcoholic polyneuritis, we desire in our communication especially to call attention to their polymorphism and to their constant existence when the disease is at its greatest height.

Soukhanoff[3] reports a case of multiple neuritis of probable alcoholic origin, in which both the methods of Nissl and of Marchi were used in the examination of the central nervous system. In the ganglion cells of the anterior horns there was marked central chromatolysis, and the nucleus was driven to an eccentric position. In a few cases the nucleus was centric with some perinuclear chromophilous substance, but about this the chromatolysis was marked. The author interprets the cell changes in two ways: In those cells with centric nuclei and with perinuclear chromatolysis the changes are probably primary, whereas in other cells the lesions are probably secondary to degeneration in the nerve fibres.

This position is, we believe, difficult to maintain.

Ewing[1] in his recent monograph reports a case with typical course, in which paralysis had been present for about two months. He found that, throughout the lumbar cord, the anterior horn cells showed all the changes described as following the section of nerve trunks. Nearly every cell showed marked central or complete chromatolysis with eccentricity of the nucleus. Many of these cells had passed beyond this stage and were entirely lacking in normal characters, containing no traces of chromatic substance, and both cell body and nucleus appearing greatly shrunken. The earlier stages of the same lesions were found in the cervical cord. Throughout the cranial nerve nuclei the majority of the cells showed central or complete chromatolysis, with eccentricity or protrusion of nuclei. Many of the cells in some nuclei, however, appeared quite normal. The nucleus *x* and nucleus ambiguus were extensively altered. The cells of the cortex and cerebellum showed only slight fading of chromatic bodies or appeared quite normal.

Heilbronner[2] has given us one of the most careful and extended studies of multiple alcoholic neuritis of recent years. In limiting his investigations more particularly to observations of the fibre and muscle pathology, his work is of secondary interest when viewed from the present general point of view of the paper, but the suggestive results obtained by his painstaking application of Marchi's method are of primary importance and demand a more careful analysis than can be here entered into. His results, as

"zusammengefasst" by himself in his four cases, are about as follows:

1. Degeneration of the anterior horns, which in Cases I. and II. showed a marked preponderance in the lumbar cord over that found in the cervical cord, while in his Cases III. and IV. the lumbar cord was affected in a minor degree compared with the involvement of the cervical cord. The dorsal cord showed but little degeneration. In those cases in which degeneration of the anterior horns was marked, a degeneration of the fibres in the anterior horn was also appreciable, and there was an involvement of the fibres of the anterior commissure.

2. There is also a degeneration in the posterior horns, involving different areas in the cases studied; in I., the cervical more than the lumbar; in II., both alike; and in III. and IV., the lumbar cord was affected the most.

3. A fresh acute ascending degeneration in the posterior columns, which in the different cases affected the columns of Goll and Burdach in different fashion. This case showed markedly greater degeneration in the columns of Burdach in the cervical region. In Case II. there was an equal degeneration in both cervical and lumbar regions of the columns of Goll, while in Cases III. and IV. the degeneration was confined almost exclusively to Goll's columns and the lumbar posterior roots.

4. Case IV. also showed a degeneration in the crossed pyramidal tracts in addition to this degeneration of the posterior columns and the posterior roots.

One fact is brought out in relation to the similarity of posterior-column degeneration to those of tabes, in that in three cases, as studied by the Marchi methods, there is no constant pathological picture, although the clinical pictures might appear identical, and that in these cases the author notes that the lesions do not exist in every root area but are found here and there, sometimes skipping a segment or segments. In this peculiar distribution of the degenerated areas is to be found one of the cardinal points of difference in the two diseases from a pathological point of view. It is possibly due to this fact also that the case of Soukanhoff gave him no positive lesions.

The lesions that Heilbronner describes as occurring in the ganglion cells, studied by the Nissl method, in one of his cases which presented the typical clinical picture and ended fatally without hyperpyrexia or other abnormal feature, are held by him to fall into two classes. The more common one was characterized by a minute disintegration of the chromatic bodies, at first about the nucleus, then about the periphery, without any variation in the nucleus; this latter, however, in the later stages would become eccentric. In a few cases vacuoles were to be found in otherwise normal cells. These he holds to be essentially different types of lesion, although he does not characterize them with reference to their causation.

The correlation of the structural changes found in this case with those induced by experimental alcohol poisoning has not proven entirely satisfactory. The earlier writers Vas and Dehio give us some interesting findings. Vas, by chronic alcohol poisoning, induced severe grades of malnutrition, which in turn, as he interpreted the lesions, produced a condition of general swelling and central chromatolysis. The findings of Dehio were more interesting with reference to the changes found in the cells of Purkinjé. In these mild grades of chromatolysis were observed. The fine chromatin bodies were largely replaced by finer granules. Stewart confirmed many of the results of Dehio. Berkley made some extended studies on acute and chronic alcoholism in rabbits. In his series of chronic poisonings alcohol was administered for almost a year in daily doses of from 5 to 8 c.c. The changes in the capillaries are reported upon, the walls of many of them being irregularly shrunken, the vascular wall nuclei being swollen and more readily stainable. In the cerebral cortex the somatochrome cells show alterations mainly in the nucleolus; here, in place of the smoothly appearing nucleolus in or near the centre of the nucleus, it appears roughened, spongy, or even with elongated projections from the surface. Not only is the nucleolus roughened, but it is also considerably enlarged, occupying from an eighth to a sixth of the interior of the nucleus, its projections extending to the periphery of the circle. Around these nucleolar figures is grouped a small amount of nuclear dust particles resembling an irregular circle, but the remaining portions of the nucleus are free from the presence of molecular particles. In the nucleus there is a decided tendency to take up more of the aniline stain. So marked does this tendency become at times that the contents are rendered indistinct and the cell body is much less refractile than normally.

In a second rabbit similar changes are noted in the blood-vessels. All of the nerve cells take up a larger quantity of the aniline dye than usual. The chromophilous granules in the cytoplasm are not so distinct; the nuclei stain a deeper hue than normally. In his series of acute alcohol poisoning of three rabbits large doses were given until a certain tolerance was established; then the doses were increased suddenly until death resulted. The Nissl method of investigation showed few definite alterations save in a few cells located in the immediate neighborhood of clogged vessels. Here the cellular protoplasm did not show its stichochrome structure: it appeared uniformly and fully granular, and besides did not take up so much of the dye as other more normal cells. In these individual cell bodies there is beginning swelling of the nucleoli, and they appear slightly roughened. The nuclear dust has not aggregated into clumps and become adherent to the nucleolus, as in some of the chronic cases of the first study. In the areas where the disturbance of the circulation has been less well defined, changes in the protoplasm and nuclei of the cells are not very positive. The stichochrome particles of the protoplasm are seen somewhat less clearly than normal, and the protoplasm as an entirety shows greater receptivity to the aniline stain than is customarily seen, or, better, they will not bleach out with the same facility that they ordinarily do. The nucleus and nucleolus appear to be strictly natural. The striated appearance of the thicker dendrites near the cell body is always seen.

These results, if they occurred in the present case, were certainly overshadowed by the changes probably induced by the peripheral disease, for, beyond some slight nucleolar fragmentation, the lesions observed were not characteristic of the findings as given by these experimental studies. In man the changes found in delirium tremens have been very various. Some observers report almost no changes at all, while others find extreme grades of cell degeneration. Perhaps none are more pronounced than those observed by Ewing.[1] He reports two cases, both of which were fatal in a condition of delirium tremens. There was some hyperpyrexia just before death, 104°–105° F. One case was complicated by acute kidney disease, the other by slight catarrhal pneumonia. These cases present a clear picture of the alcoholic poisoning. The spinal, medullary, and cortical stichochromes presented the lesion of extreme chromatolysis. No normal cells were seen anywhere, and in only a few were there any traces of the peripheral ring of chromatic bodies, often seen when the disintegrating proc-

[1] Ewing, J.: "Studies on Ganglion Cells." Archives of Neurology and Psycho-Pathology, vol. i., 1898, pp. 263–440.

ess begins about the nucleus. In many cells, especially in the cranial nuclei, the lesions had advanced far beyond simple chromatolysis, and the cell outlines were irregular and ragged and considerable areas of the cells were almost transparent. The remains of the chromatic bodies appeared as a uniform deposit of fine granules, or no traces of them could be found. In badly altered cells the nuclei were almost invariably markedly eccentric or projected beyond the cell border. They were not found to stain diffusely. Yellowish granular pigment was rarely seen in these cells. Many of the Purkinjé cells contained a moderate number of large distinct chromatic bodies, but usually these bodies are thin, ragged, granular, or absent, the deficiency being most marked at the poles and not above the nuclei. In the examination of the brain he found the following general lesions: "The cortical archyochromes showed a bleached chromatic network, though sometimes coarsely granular and indistinct."

These cases by reason of their extreme severity show marked cellular changes comparable in many ways to the lesions observed in the present case. Whether polyneuritis was beginning in these cases it is impossible to say, but the presence of the extreme grades of chromatolysis in the spinal cord throws a somewhat conflicting light on the generally accepted dicta of the process of axonal degenerations. Nor is this question of axonal degeneration made more capable of interpretation when we look at the changes in the cells of the columns of Clarke and the nucleus of Stilling. From a reference to the tabulation of the lesions found in these cells in the present case it will be noted that the cells in this region suffered as much if not more than the anterior horn cells. Such degenerations have before been noted, more particularly in other forms of polyneuritis, and especially have they been the subject of much speculation in Landry's paralysis.

Marchi[1] has shown that, following total ablation of the cerebellum in monkeys, there is a marked degeneration of the direct cerebellar tract and a degeneration of the cells of the columns of Clarke. This degeneration of Clarke's columns is distinctly homologous to the changes in the anterior horn cells following an injury to or the destruction of the peripheral end of the motor neuron. Similar changes have been noted in transverse myelitis, and recently by Barker as a result of epidemic cerebro-spinal meningitis. In this case the direct cerebellar tract was involved and the degeneration of Clarke's column was to be expected. Further we know, however, from the studies of Heilbronner and many others that degenerations of the direct cerebellar tract are found in some cases of alcoholic multiple neuritis. These cases, however, are to be classed, we believe, as fibre degenerations following cell degeneration rather than the reverse, although it must be confessed that we are entirely in the dark with reference to any knowledge of the degree of poisoning that might take place in the terminal arborizations of the direct cerebellar tract in the cerebellum.

But from this point of view, which will explain quite readily the changes observed in Clarke's columns, when the present case is studied and those of many others in which the peripheral sensory neuron is affected by the disease process and a second central neuron bears the impress of that disease, the interpretation is not so clear. Lissauer[2] as early as 1884 noted the degeneration of the cells of the columns of Clarke in tabes, and more recently Marinesco has shown the characteristic picture of an axonal degeneration in a case of tabes and general paresis; the presence of the paresis complicates this case somewhat, yet in this disease, and in others with involvement of the posterior root zone, such typical lesions are found. Sano[1] and a number of others describe similar lesions in Clarke's columns following amputation of a limb, and Sano found lesions also in the motor cortex.

In Landry's paralysis the cells of this region have been found with similar lesions by a number of writers, and more recently Mills and Spiller[2] have gone over the ground in this disease, and though believing that the entire peripheral sensory neuron may be affected by the disease, this does not explain the lesion in Clarke's columns which are connected only by collaterals with the sensory neuron. Marinesco, in his statement that he believes the changes to be secondary and like those found in polyneuritis, overlooks that the process of degeneration of the anterior horn cell of the motor neuron and those of the cells of the columns of Clarke are not homologous types of degeneration at all. We are unable to offer any explanation why the columns of Clarke should be affected, unless we assume with Van Gehuchten[3] that the ganglion cells in a nervous chain react one upon the other, and that the cutting off of the peripheral sensory stimuli produces a degeneration in the secondary spinal neuron. It is possibly true that both centralists and peripheralists are correct, and that the lesson taught by the changes in these cells in alcoholic neuritis is that the degeneration of the secondary neuron is possible only when in addition to the cutting off of its collateral stimuli the central ganglion cell is overwhelmed by some toxic influence, and yet no such toxic influence can be posited in ordinary nerve sections. With reference, however, to this latter, we might again recur to the fact that perhaps some misinterpretations have been made in estimating the degree of degeneration of the cells of the columns of Clarke. One further point of interest brought out in the present study shows that the disease of the blood-vessels may play a very secondary rôle in the neuritic process. This is quite in opposition to the views held by Fleming, who in two cases was led to the belief that the principal cause of degenerative neuritis was pressure, the result of an inflammatory exudate.[4]

Résumé: From the investigation of the present case the following general conclusions seem warranted:

1. In fatal alcoholic multiple neuritis grave variations from the normal structure (equivalent picture of Nissl) of the ganglion cells of the anterior and posterior horns, the columns of Clarke, the nucleus of Stilling, and the nuclei of the medulla are always to be found when studied by appropriate methods.

2. These cytological variations are characterized by their extreme polymorphism. They may consist of simple swelling of the ganglion cell or of its chromatin particles; fine granular disintegration of the chromatin; destruction of the chromatin; central, peripheral, perinuclear, and general chromatolysis; wandering of the nucleus to an eccentric position, and destruction of the achromatic structures to complete disintegration of the cell.

3. To what extent these lesions are due to the direct

action of the alcoholic poison on the molecular structure of the ganglion cell (primary), or the degeneration of the peripheral extensions of both sensory and motor neurons (secondary), cannot, we believe, be accurately determined. The conclusion drawn is, that the peripheral degeneration is the much more important one of the two.

4. The best hypothesis yet offered to account for the degeneration of the cells of the column of Clarke is that of Van Gehuchten, by the assumption that the ganglion cells of a nervous chain exercise the one upon the other a trophic action, the suspension of which produces a chromatolysis and disappearance of the corresponding cells.

## NOTES ON THE INDUCTION OF PREMATURE LABOR.[1]

By HENRY C. COE, M.D.,
NEW YORK.

There is such an apparent unanimity of opinion with regard to the technic of this operation that it would seem to admit of no argument. Students are taught in lectures and text-books that it is a simple matter to excite uterine contractions by artificial means, but when they attempt to apply the ordinary methods in actual practice they are often surprised and disappointed at their failure to accomplish the desired result, and are apt to attribute their ill success to lack of skill, or to the omission of some necessary details. Experience has shown that the uterus is more tolerant of rough handling than was formerly supposed. Every gynæcologist has been impressed with this fact in performing operations upon pregnant women, especially in cases of ovariotomy and appendectomy. This is well illustrated in the following cases:

Case I.—Multipara, pregnant four months, pregnancy being complicated by a large retro-uterine abscess. There was no fluctuation, and the mass was supposed to be a neoplasm or retroflexed and incarcerated gravid uterus. There were peritonitis and high temperature for several days. I made an exploratory section and found such firm and general intestinal adhesions that the incision was closed and the abscess opened per vaginam, several ounces of offensive pus being evacuated. Irrigation with hydrogen peroxide was made and gauze drainage was inserted. The temperature dropped to normal and the patient had a smooth convalescence, abortion occurring a month later, after she was up.

Case II.—Multipara, pregnant five months. She was suddenly seized with severe pain in the back and abdomen, with pressure on the rectum and inability to evacuate the bowels. On examination a tumor the size of a grape-fruit was found to be impacted in the cul-de-sac. I performed cœliotomy and removed an adherent multilocular cyst, the pedicle of which had been twisted 360°, causing intra-cystic hemorrhage and commencing necrosis. The uterus was lifted out of the cavity and covered with hot towels. The operation was long and necessitated extensive suturing of the broad ligament and peritoneal covering of the uterus. There was no reaction, the convalescence was afebrile, and the patient was up during the fourth week. She was discharged at the end of five weeks in excellent condition. Fœtal movements were active. In another nearly similar case an adherent dermoid was removed from Douglas's pouch, the patient going to full term, and having a normal labor. Such cases are now too common to cause any comment.

[1] Read at a meeting of the Harvard Medical Society, May 27, 1899.

It is usually stated that dilatation of the cervix in a pregnant woman involves imminent risk of abortion, but how often is this done without accident to relieve obstinate vomiting! Abortion has not occurred from this cause in my practice, although I always introduce the branched dilator to its fullest extent and separate it widely. Provided that the membranes are not ruptured, mere dilatation of the cervix rarely excites more than transient uterine contractions, if any.

In a recent admirable text-book on obstetrics the author seems to rely principally on the classical method of introducing a bougie. All practitioners must admit that this is more or less uncertain, and that there is considerable risk of rupturing the membranes, even at the hands of an expert—an accident which may seriously complicate subsequent attempts at artificial delivery. I recall a case in which the repeated introduction of a sound and intra-uterine faradization failed to excite contractions in a uterus pregnant three and one-half months, so that it was necessary to divulse the cervix and to remove the contents piecemeal. There remains the method of dilating the cervix and exciting uterine action by means of the gauze tamponade, with or without the subsequent introduction of rubber bags. From the trend of society discussions I would infer that the bags had fallen into undeserved disrepute. The criticisms that they cannot be rendered thoroughly aseptic, or that they are liable to do injury to the soft parts, or to displace the presenting part, seem to me to be entirely theoretical. On the other hand, it has been confidently asserted that both the gauze and bags when introduced well within the os internum invariably induce labor, but such has not been my experience, as proved by the following cases:

Case I.—Multipara with conjugate of three inches. In her first labor I was obliged to perform craniotomy upon the living fœtus, Cæsarean section and symphyseotomy being refused. In the second pregnancy I induced labor at the beginning of the ninth month. The cervix was soft and dilatable, so that the smallest Barnes' bag was easily introduced and left for several hours without result. A larger one was substituted, and finally the double McLean bag, a most valuable instrument. Thirty-six hours were spent in trying to excite labor pains. These were few and transient and then ceased entirely. Preparations were made to deliver. The bag was found to have been forced into the vagina, but the cervix was so much dilated that after a few minutes spent in manual dilatation twins were easily delivered by podalic version. There was normal convalescence of the mother, and both children thrived.

Case II.—Multipara, conjugate three and one-quarter inches. The first child was large and the cervix was rigid. There was an impacted breech with premature rupture of the membranes. Manual dilatation was made, but not sufficient to paralyze the contraction ring (a serious error), so that delay in extracting the head cost the life of the child. In her second pregnancy (again a breech presentation) I introduced two or three yards of gauze within the os internum, and substituted a medium-sized bag at the end of twenty-four hours and a large double bag twelve hours later. There were absolutely no pains, so that at the end of forty-eight hours the bag was removed and, dilatation being perfect, a vigorous child was extracted in a few minutes. Convalescence was normal.

Case III.—Multipara, with moderate contraction of the conjugate (three and one-half inches ?), but false promontory marked. In her first labor I delivered a live child by a difficult forceps operation. She became pregnant again, and I resisted the importunities of the patient and her physician to terminate the pregnancy, promising to induce labor early in the ninth month. Hydramnios and a large child. The cervix

was dilated with one finger and several feet of gauze were carried well up into the lower uterine segment. There was no result after twenty-four hours. A medium-sized bag was substituted and left in situ for twelve hours. There were no pains whatever. The patient, family, and attending physician had then become so nervous that I decided to operate. The bag had dilated the cervix about one-half, but it was easy to complete the dilatation, and a healthy child was delivered by podalic version. Mother and child did perfectly well.

Case IV.—IIIpara, enormously stout. Labors had always been difficult. She was two weeks from full term. She had had marked uræmic symptoms in her last pregnancy, and was said to have organic changes in the kidneys. She was passing a small quantity of albuminous urine, with a marked diminution of urea and constant headache. The uterine tumor was unusually large, due to hydramnios and the presence of a child above the average size. The cervix was dilatable up to the os internum, where there was marked rigidity. At least four yards of gauze were packed into the lower uterine segment. There were no pains after twenty-four hours. On removing the gauze, the double bag was easily introduced, so that it was entirely within the os internum. No pains after eight hours. Manual dilatation was completed in twenty minutes, and a nine-pound child was extracted after podalic version, the extraction being unusually difficult. There was adherent placenta, with profuse hemorrhage, requiring gauze tamponade. Convalescence was normal, and the threatening symptoms promptly disappeared.

Case V.—This case differs somewhat from the preceding, as the patient was only four months pregnant, hence the uterus may be said to have been less responsive to mechanical irritation. The patient was weak and anæmic. There were marked varicosities of the vulva, so that locomotion was difficult. Her first labor was tedious, the cervix being long and rigid. A live child was delivered by a difficult (medium) forceps operation, the cervix being so deeply lacerated that immediate trachelorrhaphy was required. The healing process was so perfect that the os subsequently looked like that of a nullipara. Early in her second pregnancy (third month) she began to have severe headache, the daily amount of urine dropping to from twenty to twenty-five ounces, while only six grains of urea to the ounce were excreted. There were no albumin nor casts. Careful diet and medicinal treatment were without result. I advised emptying the uterus, after consultation with Dr. Marx; and, having dilated with a steel instrument, I introduced two yards of gauze, which remained in situ for twenty-four hours without producing any result, except softening of the cervix. There was no dilatation whatever. The uterus was then emptied after an hour's hard work, the fœtus and placenta being removed piecemeal. It was impossible to pass one finger within the os internum. Afebrile convalescence followed. The headache ceased promptly, and the amount of urine increased in a week to fifty ounces. The patient drove out at the end of the third week.

These cases are presented simply to confirm the statement that while the gauze tamponade and water bags are invaluable for the purpose of softening and dilating the cervix and lower uterine segment, they cannot be depended upon to excite regular uterine contractions, provided that the membranes remain intact. In my opinion their use should always precede attempts at manual dilatation, save in those exceptional cases in which rapid dilatation and immediate delivery are necessary in the interests of the mother. It is more in accord with the spirit of modern elective obstetrics to deliver the patient promptly after full dilatation has been secured than to keep her in a state of anxiety for days waiting for labor to begin, until she loses both her strength and her courage, and is in poor condition to sustain long anæsthesia and an obstetric operation.

I may add that I have rarely found it necessary to anæsthetize a patient in order to introduce the gauze or bags. It is apt to demoralize the woman and her family if she is chloroformed and an "operation" is performed two or three times before the beginning of labor.

It would seem unnecessary to add that rigid asepsis is indispensable in all these manipulations. It is not enough simply to give a vaginal douche each time that the gauze is introduced, removed, and a bag substituted. Unless the same care is observed on every occasion as in a minor gynæcological operation, with regard to the preparation of the field of operation and the sterilization of hands and instruments, there will always be a painful uncertainty as to the ultimate result.

## VARIATIONS IN HUMAN GAIT.

By E. H. BRADFORD, M.D.

BOSTON, MASS.

It is important in the recognition of certain diseases to examine carefully the gait of the individual, and for this purpose a knowledge of all varieties of normal human gait is useful; it is therefore somewhat surprising that the subject is one to which comparatively little attention has been given. To walk is as natural as to talk, and to walk correctly would seem to be instinctive; but grammatical speech is not instinctive, and training can improve "form" in every exercise. When Molière's uneducated bourgeois first learned that he had been talking prose all his life, his surprise showed his unacquaintance with the subject. Perhaps attempts to classify the art of walking may excite the same amused attention.

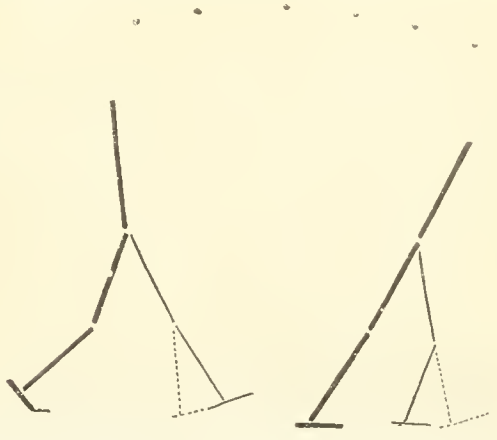

Fig. 1.—Diagram illustrating the erect and inclined gait. Dotted lines indicate the position of the leg in the variations; the upper dotted line indicates the rise and fall of the head at different portions of the gait.

Human gait is ordinarily divided into the walk and the run, the distinction between the two being based on the fact that in the former one foot is always on the ground, while in the latter both feet may be in the air at the same time. The walk, however, can be subdivided according to the force used in propelling the trunk forward, and the manner in which that force is used.

The varieties are as follows: first, the upright gait, which is commonly seen in adults walking on an even surface. It is characterized by the erect position of

[1] Read before the centennial meeting of the Medical and Chirurgical Faculty of Maryland.

the trunk and the firm planting of the heel of the forward leg upon the ground. The trunk is pulled forward by the muscular action of the glutei and the hamstring muscles, and this is aided by the push of the rear foot. This gait is seen in all cities and is common among shoe-wearing people. It is exaggerated in people the muscles of whose feet are weakened by shoes, and by a life of leisure. In this gait, the front of the forward foot is used but little, and of the rear foot only at the end of the stride. The gait, consequently, taxes the muscles of the soles of the feet governing the action of the toes and the front of the feet but slightly. This gait can be easily recognized by the erect position of the trunk, with the head well behind the striking-point of the front heel. In exaggerated cases there is added to this an exaggerated toeing out of the feet and an unusual angle of the foot formed with the plane of the ground as the heel strikes the ground. The erect gait is common in corpulent persons and in persons walking down an incline.

Fig. 2.—Illustration of the erect gait.

Fig. 4.—Diagram indicating the side inclination of the trunk in the variations in gait, according to the varying strength of muscular groups; dotted line indicating the line of side oscillation in the sway of the body.

The second form of gait is usually seen in barefooted individuals, and is characterized by the utilization of the weight of the body falling forward as a means of propulsion. The body is inclined forward from a stationary point, and would fall forward if this was not checked by the forward leg thrust out to prevent the fall. The heel of the front foot may or may not strike the ground first, but if it does, it is immediately followed by the whole of the sole and the toes. Ordinarily, however, the front foot catches the weight on the whole sole. The front of the foot pressing upon the ground presses the inclined body forward, and in barefooted or moccasined individuals and on soft ground, the pressure of the toes pulls the body forward, progression being also aided by the push of the rear foot at the end of the stride. The heel is but little used as a point by which the body is pulled forward, but the front of the foot is largely used, somewhat as in animals, to claw the ground. This gait is characteristic of barefooted and moccasined people.

Fig. 5. Diagram indicating the rotation of the trunk in walking, and the swing of the arm.

Fig. 3.—Illustration of the inclined gait among barefooted savages of Western Africa.

It is common in young children and is seen in persons in snow-shoeing, walking in slippery places and up a

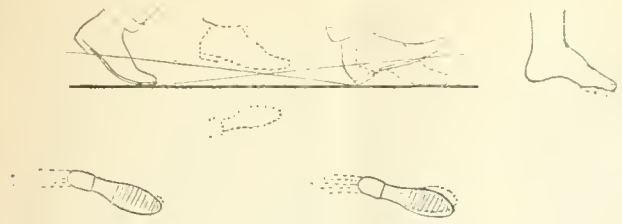

Fig. 6.—Diagram of the varying positions of the feet in different portions of the gait, and of foot impressions in walking in the snow.

sharp ascent, and against a strong wind. The knees are usually slightly bent, and strain comes upon certain muscles of the leg not used in the other variety of gait, that is, in the muscles of the soles of the feet and the front of the thighs. Less strain comes upon the muscles of the calf, as the weight of the body is not

Fig. 7.—Photograph of footprints in snow.

rested on the feet, but chiefly upon the knees. As the heel does not strike the ground with a straight limb there is less jar on the spine, and as the body falling forward is utilized as an aid to propulsion there is a muscular economy in this gait.

A combination of these two gaits is seen in strong and active walking, the weight of the falling body being utilized, but the stride is long, a strong push of the rear leg being used.

Variations in the details of gait are seen in the angle with which the front foot strikes the ground, the straight or bent position of the forward and rear leg at the extreme limits of the stride, the angle of divergence of the foot, that is, the angle formed by the axes of the feet seen from the front or from behind, the height to which the rear foot is raised as it

Fig. 8.—The variations of the position of the feet seen from the front.

leaves the ground, the straight or inclined axis of the rear and front foot with the vertical plane, and the divergence and inclination of the foot as it is swung forward. These variations, when slight, are of but little practical significance, caused as they are ordinarily by habit and by the different strength of different individuals. It may be stated that the stronger the foot and the stronger the gait, the less the angle of divergence and the more near to the central line and horizontal plane the foot moves. Variations are also to be seen in the sway of the body, the swing of the arms, the rise and fall of the trunk, and the rotation of the axes of the pelvis and the thorax. These slight variations may in paralytics become exaggerated, indicating the weakness of certain muscles and causing a limp, dragging of the foot, swaying of the trunk, or unusual position of the feet. The toeing out of the feet either in standing or in walking is a convention-

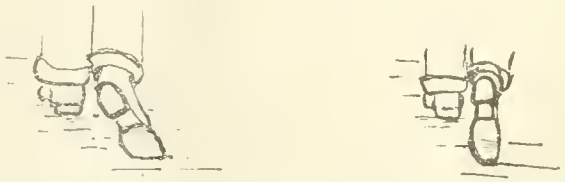

Fig. 9.—Variations in the inclination of the axis of the foot seen from behind.

ality if carried beyond a slight degree. Persons with normal strength of the muscles of the leg and feet can stand with the feet straight as steadily as with a slight divergence of the axis of the foot, but in shoe-wearing people in whom the action of the front of the foot is weakened, a slight amount of toeing out broadens the base of support and is of use to prevent swaying of the body, and in leisurely gait in which the muscles are relaxed and those of the foot are not much used, a slight amount of divergence of the feet is normally seen even among barefooted people, as, owing to the attachment of the psoas and iliacus muscles to the inner side of the femur, when the thigh is swung forward it would turn out slightly. This is checked and corrected in a strong gait in which the muscles of the front of the foot are actively and firmly used.

In order to detect pathological changes in the muscles of the feet and legs, it is necessary to study more closely the motions of the feet in walking. When the front foot strikes the ground in the ordinary erect gait, the heel strikes first: as the body comes forward the front of the foot strikes and remains in contact with the ground till by the forward motion of the trunk and other limb the front foot has become the rear foot; the heel is raised in the final push, and the rear foot is swung forward. The foot is swung forward clear-

Fig. 10.—Spanish prisoners embarking at Santiago, showing the gait of exhausted men. The figure in the centre is of a Cuban and indicates the leisure gait of strength. The figure to the left is that of a American soldier.

ing the ground, moving with the heel on a descending line until it strikes the ground, the toe or front of the foot being raised as the foot is pushed forward. In some individuals the heel is first raised quite high in the final push of the rear foot, in others is raised but little, and the front of the foot by a motion at the ankle joint is raised considerably. In the latter instance considerable strength of the muscles of the front of the leg is indicated. A singular change in the direction of the foot takes place as it is swung forward. When it is raised from the ground as the rear foot the axis of the foot may be vertical to the ground or at a varying angle, the heel dropping slightly inward, as the foot is brought forward the toe is raised and the whole limb turned slightly outward by the action of the psoas and iliacus already mentioned, so that just before the heel strikes the ground the foot turns outward more than when the heel is first raised from the ground. As the front of the foot is brought down upon the ground it is more nearly straight than when swung forward. In persons with but little play in the medio-tarsal articulation, or in whom the muscles of the leg and foot are weak, the foot is but little turned in after the heel strikes the ground producing a flat-footed gait. Under these circumstances in aggravated cases the final push at the end of the stride is weak and a shuffling gait results. In strong-muscled people, especially when barefooted, there is but little outward swing of the foot as it is brought forward and often slight toeing-in of the front of the foot as it strikes the ground; the greater toe spreads to the inside in order to grasp the ground as an aid in propulsion characteristic of barefooted or moccasined people. The swing of the foot of shoe-wearing people can best be seen in watching the tracks of individuals who have walked in freshly fallen snow, where the snow-fall is not so deep as to give the gait the act of wading. It will be seen that as the foot is brought forward, the heel descends on an incline until it strikes the ground, causing a track by disturbing the snow which appears attached to the footprint. This track in the snow is always in the direction in which the individual is going and forms an angle with the axis of the footprint of the foot, the amount of the angle being dependent upon the amount the individual toes out. Light snow with a depth of a fall of two inches will in certain instances show the track of the toes of the foot as it is swung forward. This is seen somewhat to the outside of the line of descent of the heel and behind it, and will be noticed as a curved line joining the line of the descending heel. This will not be seen in strong or vigorous walking, in which the feet are brought forward in a straight direction and without an outward swing.

FIG. 11.—Photograph of the soles of the feet, one of an individual who has worn shoes, showing the weakened muscles and the cramped condition of the toes; the other of an individual who has never worn shoes, showing the strong condition of the foot muscles and of the toes. Photograph from the Caroline Islands.

The old writers have claimed that in the normal gait the front of the foot strikes the ground at the same time that the heel does, and this is taught as the parade step in some armies. The fallacy of this has been completely proved by instantaneous photographs, and the step is unserviceable in the erect gait where the heel is meant to strike the ground as a point by which the body is to be pulled. It is, however, characteristic of strong walkers that the front of the foot strikes the ground after as short an interval as possible following the impact of the heel, in order that the pressure of the front foot upon the ground may be as strongly used as possible in the muscular effort of propulsion. It is for that reason that the striking of the ground with a high angle of the foot is to be avoided and is indicative of an untrained gait. The striking of the ground with the knee of the front foot bent is also indicative of an untrained gait in that the stride

FIG. 12.—Gait of baboon, showing the claw-like action of the toes.

is thereby shortened, unless the gait is of the second variety in which propulsion is not gained by the heel of the front foot so much as by the falling forward of the

FIG. 13.—Photograph of a child beginning to walk, showing the claw-like position of the toes.

weight of the trunk. A long stride may be gained in the second variety of gait by allowing the body to fall more completely, but it is checked by the forward leg. A long stride therefore in this variety of gait is obtained only by the expenditure of a greater strain on the muscles of the front of the thigh, and it is for this reason that a short stride is for ordinary use preferable in this variety of gait.

The swaying of the body sideways varies according to habit and muscular strength. When the muscles are all strong there is but little side sway; when the muscles that hold the trunk upon the thigh are weakened the body will swing to the outer side as the weight comes upon the leg to diminish the strain upon these muscles. Not infrequently, however, when the individual pushes with the rear foot somewhat obliquely, the whole figure is pushed from the ankle upward to the outer side and slightly forward. In the ordinary gait there is but slight rise and fall of the hips as the weight comes alternately upon one foot or upon the other, but in some individuals this may be considerable.

The amount of rise and fall will depend upon the length of the stride and also upon whether the knees are bent and straightened in the different parts of the step. In a shuffling gait there are but little rise and fall; in a strong stride the rise and fall are uniform and considerable.

The cross axis of the pelvis is held during the walk at right angles to the direction of motion, and a slight sway takes place as the foot is thrust forward. In track walking this is artificially exaggerated in order to lengthen the stride, the individual swinging forward and the front of the rear foot twisting his pelvis forward in the direction of the front foot. As the legs are thrust forward in ordinary gait a compensatory swing of the arms takes place, the arm opposite the protruding leg being swung forward. The amount of this swing depends upon the rapidity of the gait and the activity of the stride.

These less important variations need to be carefully noted by any one wishing to familiarize himself with the peculiarities of gait, but for the practical purpose of the clinician it is necessary to bear in mind only a few of the points herein suggested, as follows: that there are two varieties of human gait besides what is known as a run, and that of these that in which the body is held erect, the weight being well behind the front foot, is the most common in civilized communities. The other variety is common among barefooted savages. That in the erect gait the heel of the front foot is important as a means of pulling the body forward, as is also the front of the forward foot as soon as the weight of the trunk is brought over the forward leg; the front of the rear foot is also used as a means of propulsion in the final push.

The importance of the front of the foot in gait should lead to greater care in construction of footwear, and in the prevention of weakening the muscles by shoes; and in gymnasiums, and in training men for marching, greater attention should be paid to the development of the muscles regulating the front of the foot, in the toes, and in the development of muscles that will enable them to utilize the forward gait. Troops sent in rapid pursuit of Indians or moccasined people should be trained in such a way that they should not be outclassed by the special muscular development of the people who can utilize thoroughly the economy of their forces in walking.

133 NEWBURY STREET.

## Progress of Medical Science.

**The Employment of Yeast in the Treatment of Vaginal Blennorrhœa.**—In seeking for a method capable of destroying gonococci and their toxic products, without deleterious effect upon the patient, Landau (*Deutsche medicinische Wochenschrift*) found that common yeast fulfilled this requirement. Of forty cases of vaginal blennorrhœa treated according to this principle cure was effected in more than half, in some after one or two applications. In others temporary relief was afforded, and the discharge returned; in still others the catarrhal affection was ameliorated; and in a few cases there was no apparent improvement, although the patients declared that they felt better. The yeast was obtained from a brewery, and, after being diluted with a small quantity of beer, was injected into the vagina with an ordinary syringe, and retained by means of a tampon closing the orifice of the canal. The injection was repeated after two or three days and the treatment was continued for several weeks.—*Lancet.*

**The Bearing of the Neurotrophic Function on Cutaneous Conditions.**—In an article by Dr. Samuel Wolf (*Philadelphia Medical Journal*, March 25th), what the writer has designated as the neurotrophic function is first described as a term to represent the action of the nervous system on metabolic processes. He then reviews the various classes of cutaneous affections which are due to impaired nervous conditions. Seven classes are made to cover the field, and the following conclusions are formulated: (1) That trophic powers or metabolic properties are inherent in the tissues themselves. (2) That these are related in highly specialized organisms to impulses generated in gray nervous matter in the ganglionic systems of the cerebrospinal axis and the sympathetic. (3) That the impulses arising in the brain and cord are anabolic in their character, while those arising in the sympathetic

are katabolic. (4) That the impulses are in each case conveyed over special fibres adapted to their function by virtue of their central and peripheral terminations. (5) That the field of dermatology offers exceptional and remarkable opportunities for the study of neurotrophic processes.

**Pulmonary Emphysema.**—Dr. Samuel Gee closed his lectures before the Royal College of Physicians of London in March last with the following remarks: "To end our inquiry by recapitulating the results at which we have arrived, I submit to your judgment these propositions: That pulmonary emphysema is chiefly due to forced inspirations, although forced expiration may to some small extent play its part. That the distention of the lung in so far as it is due to inspiration is secondary to distention of the chest. That the forced inspiration is rendered necessary by a feeling of dyspnœa. That the dyspnœa which occurs at the beginning of pulmonary emphysema and which determines it is consequent upon obstruction of the air passages. That in chronic progressive emphysema this obstruction depends upon bronchitis, either humid and attended with free secretion or dry with scanty secretion. That when once emphysema is set up, the dyspnœa and the necessity for forced inspiration are increased by the natural defect of expiratory power in the lungs and in certain parts of the chest, nature having provided means insufficient for reducing excessive inspiratory distention to the normal and for thus emptying the lungs of residual air. That the degeneration and atrophy of lung tissue are usually dependent upon preceding overdistention, although it is possible that pulmonary atrophy may to some extent be primary. Allow me to conclude by appropriating the words of the most ancient of the Greek philosophical poets, 'These opinions have seemed to me to resemble the truth.'"—*Lancet*, March 25th.

**The Education Treatment of Neurasthenia and Certain Hysterical States.**—In an essay upon the severer forms of neurasthenia and allied conditions, Dr. Morton Prince (*Boston Medical and Surgical Journal*, October 6, 1898) summarizes the general mode of procedure advised by him as follows: (1) Instruction of the patient in the nature of the symptoms and disease. (2) Fixed ideas, apprehension, and erroneous beliefs counteracted; faulty habits of temperament and character corrected. (3) Individual symptoms suppressed by electricity, suggestion, and other therapeutic agents. (4) Rules given for the daily conduct. (5) Improvement of nutrition, moderate rest, and, in extreme cases, isolation from previous surroundings only. The principle is, see that enough rest is given, and being satisfied of that, see that the remainder of the time is spent in education and training, and provide as much hygienic occupation as the patient will stand. If a neurasthenic cannot sit up ten minutes, she can one, which will soon become ten. If she cannot drive twenty minutes she can ten.

**Common Soap as a Disinfectant.**—Experiments made by Serapin in Padua (*Annal. d'Igiene Sperimentali*, 1898) to determine the disinfecting value of various soaps show ordinary varieties not inferior to those claiming to be highly disinfectant. The former, however, vary greatly in exact value. White or marbled hard, pure castile containing little water appears to be the best. Solutions of three-per-cent. or four-per-cent. strength are efficacious when other disinfectants are not available.

**Anæsthetics and Urinary Secretion.**—Prof. W. H. Thompson made a preliminary communication on this subject before the Royal Academy of Medicine of Ireland, of which the following is a brief summary: (1) A mixture of ether and chloroform (2 to 1) did not cause an increased diuresis. This was the anæsthetic used in his sodium-chloride research. Six experiments were performed on dogs. (2) A. C. E. mixture, on the contrary, did in most cases markedly increase the amount of urine. In one case suppression was caused. This dog proved to have albuminuria. (3) Ether also produced an increase of urine, as did chloroform likewise, but with this latter anæsthetic only one experiment had so far been carried out. (4) Little or no effect was produced by the various anæsthetics on the total output of nitrogen and of urea, even in cases in which marked diuresis was caused. (5) The after-effect on the output of chlorides showed a marked diminution. What the immediate effect was had not so far been definitely decided. (6) In eight experiments (with different anæsthetics) the urine was examined for carbohydrates with chloride of phenyl hydrazin and sodium acetate. All but one gave crystals. Some of these were undoubtedly glucosazone, others glycuronic acid, while in one case it is probable the crystals were those of galactosazone. In all cases the dogs were injected with a solution of morphine.—*The Medical Press*, March 22d.

**Inoperable Tumor.**—Dr. William Mitchell (*British Medical Journal*, February) recommends moist compresses of formalin. It diminishes the secretion, suppuration, and the hemorrhage from perforating ulcers. Repeated applications cause the formalin to penetrate into the tumor, producing coagulation, and permitting the use of the scalpel and sharp spoon in the removal of considerable portions of the growth without causing bleeding.

**For the Prevention of Post-Scarlatinal Diphtheria.**—Garratt and Washbourn (*British Medical Journal*, April 15, 1899, p. 893) maintain that post-scarlatinal diphtheria is due to the association of unrecognized cases of diphtheria with patients suffering from scarlet fever, and that this can be obviated only by systematic bacteriological examination of the fauces in cases of scarlet fever, and separation of those in whose throats diphtheria bacilli are found.

**Pseudo-perityphlitis.**—Under this title Nothnagel (*Wiener klin. Wochenschrift*, March, 1899, No. 15) describes a case of hysterical perityphlitis occurring in a patient twenty years of age. For the past two years signs of a chronic appendix trouble were shown, and a laparotomy was performed, on the occurrence of some of the symptoms of an acute diffuse peritonitis. The operation showed a normal peritoneum and no local cause for the symptoms. There remained, however, a constant pain in the ileocæcal region; there were no pain and no fever and no signs on palpation with the exception of a marked hyperæsthesia. The author terms this a pseudo-typhlitis hysterica.

**Vulvitis in Children.**—Dr. Drummond Robinson, before the Obstetrical Society of London, which met January 4th, reported the results of his investigation of fifty cases of vulvitis in children, in seventy-six per cent. of which were found cocci similar to the gonococcus of Neisser. Dr. Handfield-Jones found it difficult to believe that over seventy per cent. of all vulvar discharges in children depended on gonorrhœal infection. The following points seemed to him to render the gonorrhœal theory doubtful: (1) The disease had not spread to neighboring tissues; (2) it was readily cured; (3) the inguinal glands were rarely enlarged; (4) the disease was common in delicate, rare in robust children; (5) in undoubted infection during rape the disease was much more severe than in ordinary cases of vulvitis.

MEDICAL RECORD:

## BULLET WOUNDS IN MODERN WARFARE.

IT is safe to say that since the introduction of the small-calibre rifle and smokeless powder the conditions of warfare have undergone an almost complete change. Until our war with Spain little was definitely known of the effects produced by wounds resulting from a bullet fired from a modern rifle. Indeed, with the exception of the experience of the British gained in Indian frontier wars, our knowledge in regard to the latest patterns of small arms may be said to have been practically *nil*. Much valuable information was gathered during the fighting in Cuba. And the battles and skirmishes now continually taking place in Luzon will undoubtedly furnish further and more precise evidence in regard to the comparative deadliness of the old and new weapons and to the difference in the character of the injuries inflicted by them. The Filipinos, as were the Spanish, are chiefly armed with the Mauser, an excellent type of the up-to-date rifle. The penetrating power of the Mauser bullet of the pattern of 1897 is, according to Major Legarde, 35.125 inches. The Krag-Jorgensen of 1898 penetrated 26.125 inches, while the Springfield could send a bullet only six inches through the same thickness of wood. The velocity of a bullet expelled from a Lee-Metford is nearly equal to that of one from a Mauser. What then are the consequence and nature of an injury produced by a bullet travelling at such a marvellous speed? Brun's experiments led him to believe that at ranges over three hundred metres the small-calibre bullet hardly ever becomes deformed, while between four hundred and fifteen hundred metres it as a rule makes a wound with a very small passage, with very small apertures at the points of ingress and egress and with very little shattering of bones or tearing away of the soft parts. Stevenson says the velocity of the bullets since 1865 has greatly increased and consequently in the same ratio its energy or impact. With increased velocity they have gained enormously in penetration, but if they do not reach a vital part or strike a large bone, they do not disable. With respect to the character and gravity of a wound the same authority remarks: "When a bullet has passed through soft parts only, the exit wound is usually a circular punctured-out hole, but its edges are slightly shreddy and torn. . . . The nearer the bullet strikes the bone at its greatest diameter the greater is the destruction produced both in the bone and in the soft parts beyond; but even with grazing shots most severe splintering of the bone and extensive pulping of the soft parts are observed."

Dr. Davis, speaking from his experience in the Greco-Turkish war, reaches the conclusion that the initial force of a bullet is an onward or penetrative one; that when penetration is impeded the onward force becomes transformed into a lateral one; that explosive effect is only another name for lateral action, *i.e.*, outside the track of the bullet; that lateral action is most marked in hard bones (the fragments being carried onward) and in organs containing water (bladder, brain, liver, etc.); that practically the rotation of the bullet on its axis does not materially affect the character of the injury; that the effect of gunshot wounds is not so severe upon the living body as upon the dead; that the destructive power of the small-calibre gun has been overestimated; that its stopping or disabling power is less than that of larger calibres; that wounds in future conflicts will be as a rule less severe and will heal more rapidly, with fewer complications, than has been the case in the past; that less radical treatment will be required, and conservatism will be followed by brilliant results. The foregoing views have been quite recently corroborated in many respects by the army surgeons in the Philippines. Surgeon Beck, of the Thirteenth Minnesota, says that "to the small-calibre bullet of the insurgents' Mausers the wounded boys owe their lives and a continuance of their usual friendly association with good arms and legs. In the bony structure of the body the Mauser bores a clean little hole, rarely fracturing a limb; in the skull it takes a centre shot to kill." He says that he has knowledge of fully a hundred men shot through the chest cavity in every portion except the heart, who recovered. But while the injuries brought about by bullets from the army rifles of to-day are on the whole less severe than was formerly the case, abdominal wounds are as fatal, if not more so, than in former times. Surgeon Beck says: "Through the soft abdominal tissues the Mauser is always fatal. Wounds of the intestines, stomach, and spleen always kill. Every operation for resection of wounded intestines resulted in death, and the operation is now entirely abandoned." This is in line with the opinion of a large number of army surgical authorities, although views differ considerably as to whether in penetrating wounds of the abdomen a radical or conservative treatment should be pursued. Dr. William Parker, of New Orleans, discussing this point, records his belief that in abdominal wounds caused by the small modern bullet laparotomy should not be attempted in the field. Dr. Nicholas Senn lays down the dictum that laparotomy in penetrating gunshot wounds of the abdomen is indicated in all cases in which life is threatened by hemorrhage of visceral wounds, and the general condition of the patient is such as to sustain the expectation that he will survive the immediate effects of the operation. And Sir William MacCormac advises, when penetration has been diagnosed, that abdominal section should be performed as quickly as possible. The fact, however, may be noted here that the mortality which has up to

the present followed penetrating wounds of the abdomen treated on the battlefield or in war hospitals has been extremely high. The French lost 91.7 per cent. of their cases in the Crimea, and the English 92.5 per cent. In the American war the death rate was ninety per cent. From a consideration of the facts arrived at in regard to the bodily damage inflicted by the small-calibre bullet in the Spanish-American, Greco-Turkish, Philippine, and Indian frontier wars these conclusions may be laid down:

That while the modern army firearm leaves nothing to be desired as a humane weapon, it hardly fulfils the special purpose for which it has been designed.

That owing to the velocity with which the bullet of a modern rifle travels there is but little fear of pieces of clothing being carried into the wound, and in consequence the danger of infection by these means is very considerably reduced.

That the wounds produced are as a rule much less serious than when bullets of a larger calibre are used.

That the velocity of a bullet fired from any one of the new rifles is so great that it does more damage at a distance than at close quarters.

And, lastly, that abdominal wounds effected by bullets fired from weapons of the newest type are in a high degree fatal.

## THE EMPLOYMENT OF ANTISTREPTOCOCCIC SERUM IN THE TREATMENT OF SMALL-POX.

While in many, if not all, infectious processes serious consequences and even death may result from the primary disorder, there is abundant clinical and pathological evidence that these occurrences are favored and sometimes actually brought about through the agency of secondary infections, and it has been thought that if the latter could be averted or mitigated a great end would be attained. Observations in support of this view were made by Dr. W. J. Lindsay, resident medical officer at the Middlesbrough Isolation Hospital, in the course of an epidemic of smallpox in the English town and district of the same name, during the earlier months of the year 1898 (*British Medical Journal*, May 13, 1899). It was found that death occurred most frequently during a period of from three to five or seven days after the pustules began to dry and be absorbed, and it was concluded that the purulent change was due to pyogenic organisms entering the vesicle from without, and to the absorption into the circulation of the toxic products to which the untoward results were in some degree due. It was found that by rigid antiseptic treatment suppuration in the vesicles could be prevented, but the procedure was difficult of application and the results were not entirely certain. Resort was, therefore, had to antistreptococcic serum, injections of which at intervals of from twelve to twenty-four hours were made aseptically into the subcutaneous tissues of the abdominal wall, either just before or coincident with pustulation. Six cases in which the lesions were confluent and the prognosis was grave were selected for the treatment, with the result that the critical period following the absorption of the pustules was shortened, the intensity of the toxæmia lessened, and the tendency to cardiac failure and collapse diminished. The pulse throughout, though fast, was regular; and the strength of the beat was well maintained. Convalescence set in earlier and progressed rapidly. In two of the cases death resulted; in the remainder no abscess formed.

## THE MANHATTAN MEDICAL SERVICE COMPANY.

There has recently sprung up in this city a most pernicious method of deluding the public and of cheating the physician of his just dues. The Manhattan Medical Service Company is referred to. This company, formed and conducted by Guy Otis Brewster, M.D., as president, with M. E. Brewster as vice-president, promises for the munificent fee of two dollars a year to treat at the consultation offices, in upper Madison Avenue (with an average charge of twenty-five cents for medicine), any person between the ages of sixteen and forty-five years. Further than this, if patients prefer to be treated at their own homes, the services of what is termed the company's district physician can be requisitioned, the charge for this attendance being ten cents weekly. The said district physician receives five dollars per hundred for all contracts issued by the company in his district, and seven dollars per hundred for all prescriptions written by him. He is also directed to make his prescriptions as simple as possible, and to use no proprietary drugs on account of the expense. The physician, however, who is unfortunately for himself inveigled into becoming an employee of this company, soon discovers that he does not even get the amount stated in the contract, for these contracts, which he was given to understand were to be single, are in reality family ones, so that he is expected to treat families irrespective of numbers for fifty cents per annum, with seven cents for each prescription he gives. Confinements and venereal diseases are inclued within the same contract. There are no troublesome restrictions with regard to ability to pay or otherwise in connection with the Manhattan Medical Service Company, but so long as the subscriber hands over ten cents per week he is entitled to medical treatment and medicine. This is not all: if the subscriber's illness is serious he will be received into the sanatorium on Madison Avenue, where he will be furnished with the most skilful medical and surgical treatment obtainable in New York City (?), doubtless at an exceedingly low cost, although the directors of the company are careful not to mention the rate of payment for sanatorium treatment. This scheme strikes us as an impudent attempt to fool the public, while at the same time it must seriously injure many struggling young medical practitioners. We trust that by a showing up of the methods of the Manhattan Medical Service Company the eyes of both the medical profession and the general public may be opened to the iniquity of their proceedings.

## News of the Week.

**Dr. W. F. Brunner,** recently United States sanitary inspector at Havana, has been appointed health officer at Savannah, Ga.

**Aid to the British in South Africa.**—The statement is made that the Boers in South Africa consume large quantities of patent medicines of American manufacture. Thus do we seek to aid the Anglo-Saxon by undermining the Boer constitution.

**Smallpox Epidemic.**—The inspector of the State board of health on June 27th reported fifty-six cases of smallpox at Utahville, a mining village of Pennsylvania with two hundred inhabitants. The disease has prevailed since February, when it was supposed to be chickenpox.

**Holders of New Jersey Licenses can Practise Medicine in Delaware.**—In accordance with an amendment to the State medical law adopted by the last legislature, the medical council of Delaware will hereafter recognize the certificates of license to practise medicine issued by the New Jersey State board of medical examiners.

**The Study of Tropical Diseases in Germany.**—The new German school for the study of tropical diseases is to be established at Hamburg. It was designed at first to locate the school in Berlin, but was afterward decided to establish it at one of the larger seaports having trade with tropical countries, and Hamburg was selected.

**Sweat-Shop Reform.**—An amendment to the factory inspection act in Pennsylvania permits of the confiscation of the clothing found in process of manufacture in unsanitary places. On the occasion of its first enforcement a short time ago, a woman was found engaged in sewing on children's clothing in the same room with a child lying ill with diphtheria. Hitherto the maximum penalty for infringement of the law was a fine of $20, but the punishment was not heavy enough to be a deterrent to a rich proprietor, especially as the law was seldom enforced. Now, however, the confiscation of the clothing, added to the money penalty, is expected to influence the dealers to exercise more careful supervision over the places in which their wares are manufactured.

**Recommendations of the State Board of Health in Regard to Consumptives.**—The board of health of Saranac Lake, by a resolution passed June 27th, has indorsed the action of the New York State board of health directing all local health officers to register the name, address, sex, and age of every person suffering from tuberculosis in their respective jurisdictions; and providing that in all cases in which it comes to the knowledge of the health officer that premises which have been occupied by consumptives have been vacated by death or removal, the premises must be visited, directions given as to disinfection, removal of carpets, rugs, bedding, etc., and such further directions given as may be deemed necessary, which must be enforced for sanitary reasons, and that no person shall be allowed to occupy such apartments until the order of the health officer is complied with. It has also indorsed the recommendation of the State board that formaldehyde be employed as a disinfectant of houses and textile fabrics.

**The Lane Lectures.**—The fourth course of ten lectures, founded by Dr. L. C. Lane, was delivered at Cooper Medical College, San Francisco, by Dr. N. Senn, on June 28th to July 3d. The lectures were on shock, hemorrhage, wounds, fractures, and amputations.

**An Example not to be Followed.**—Dr. Klebs has opened in Chicago a private free dispensary for the poor, thereby introducing the German custom into this country. Certainly he deserves no thanks from the medical profession for this innovation, especially as we are just now seeking a remedy for the surplus of existing dispensaries in our cities.—*Cleveland Journal of Medicine.*

**A Supposed Plague Ship at San Francisco.**—The steamer *Nippon Maru*, which was reported from Honolulu with plague aboard, arrived at San Francisco last week and was immediately quarantined. The passengers have sent a protest to Washington against their detention, asserting that there is no proof that the passengers who died *en route* were victims of the plague.

**A Candy Investigation.**—An analysis was recently made by the board of health of nearly two thousand samples of candy of all kinds, purchased at different stores in this city, but chiefly from street stands and little shops in the vicinity of the public schools. According to the report, none of the samples submitted contained any insoluble or harmful materials. The chief ingredients of the cheaper grades of candy were found to be starch, sweet gum, and glucose.

**Object to Safety Lamps.**—A year and a half ago an explosion occurred in a mine near Wilkesbarre, Pa., whereby five of the engineer corps, a fire-boss, and a miner, seven in all, lost their lives through the careless use of a naked lamp. A strike is now in progress at this same mine, the object being to defeat the attempt of the company to compel the miners to use safety lamps.

**Prosecution of a Quack.**—A man calling himself Clarence Foster was recently held for trial in the Yorkville court on two complaints of practising medicine without a license. He has been connected with a "dermatological institute" in Twenty-third Street and is also said to have had an office in Fifth Avenue, practising there as Dr. Efil. The County Medical Society has for a year been trying to get evidence against him. When arraigned, he admitted that he was not a physician and that "Dr. Efil" was a myth. He claimed in his defense, however, that he gave only patent medicines. He was held in $500 for trial.

**The Opticians Protest.**—The Optical Society of the State of New York at its annual meeting last week passed some resolutions protesting against the condemnatory resolutions of the American Medical Asso-

ciation at Columbus and of the American Institute of Homœopathy at Atlantic City, and declaring that the society believed that "the honorable occupation of an optician entitles him to the same courteous consideration at the hands of medical men as that now accorded to those following dental and other mechanico-scientific callings."

**Tuberculosis Sanatoria in Germany.**—Baron Hoyl zu Horrnshein, the National Liberal member of the Reichstag, has donated 3,000,000 marks to the fund for the erection and maintenance of sanatoria for the treatment of tuberculosis in the poor.

**The Canadian Medical Association.**—The annual meeting of this association will be held at Toronto on August 30 and 31 and September 1, 1899. The general secretary of the association is Dr. F. N. G. Starr, of Toronto.

**American Medical Editors' Association.**—At the annual meeting of this association, held at Columbus in June, the following officers were elected for the ensuing year: *President*, Dr. I. N. Love, St. Louis, Mo.; *Vice-President*, Dr. J. E. Brown, Columbus, Ohio; *Secretary*, Dr. Dillon Brown, New York; *Treasurer*, Dr. Alexander Stone, St. Paul, Minn.

**Officers of the New Jersey State Medical Society.**—At the meeting of the Medical Society of the State of New Jersey, held at Allenhurst, June 27th, 28th, and 29th, the following officers were elected for the ensuing year: *President*, Dr. Luther M. Halsey, Williamstown; *Vice-Presidents*, Drs. William Pierson, Orange, John D. McGill, Jersey City, and E. L. B. Godfrey, Camden; *Corresponding Secretary*, Dr. E. W. Hedges, Plainfield; *Recording Secretary*, Dr. William J. Chandler, South Orange; *Treasurer*, Dr. Archibald Mercer, Newark.

**Yellow Fever** has appeared at Salvador in Central America. The epidemic still continues at Vera Cruz, and cases are reported from Tampico and other places on the Mexican Gulf coast. The marine hospital service has sent an inspector to reside at Vera Cruz for the present in order to keep a check on all passengers and notify the United States quarantine inspectors of all persons who come from the infected districts. He will also arrange a system of issuing certificates to all railway passengers who desire to enter the United States, reciting the movements of the passenger and baggage for a period of ten days previous to entry into the United States. The marine-hospital service treats every place south of Vera Cruz to the Guatemala border as infected, and it is believed that the danger to this country during the present summer is in Mexico rather than in Cuba. The disease is thought to be decreasing in Santiago, where there were ninety-five cases and twelve deaths up to July 3d. Almost all the cases have been among United States troops, who are believed to have become infected either in the old Spanish barracks or in an old building in which there is a drinking-saloon much frequented by the American soldiers. Havana is declared to be as free of yellow fever as New York, furnishing a striking illustration of what cleanliness can do even in an unsewered city inhabited by people to whom the name of sanitation is as unfamiliar as the English tongue.

**The Food of the German Soldier.**—The German soldier used to be given only two meals daily, namely, breakfast and dinner. The latter meal was given at eleven o'clock in the day, and from that hour till breakfast the following morning he had nothing to eat except what he was able to provide out of his own pocket. On January 1, 1897, however, a step forward was made, and the soldier was given two evening meals in the week; the further additional meal for the remaining five days has now been granted, and for the future the German soldier will be served daily with a substantial evening meal.—*British Medical Journal.*

**An International Congress on Medical Ethics** will be held in Paris during the week of July 23–28, 1900, immediately preceding that in which the International Medical Congress will be held. From a notice in *The Lancet* we learn that the congress will be divided into four sections. The first will deal with the relations of medical practitioners with large bodies, the State, the municipalities, etc. This comprises: (1) relations with the State, organizations depending directly on the State, and the laws regulating medical practice; (2) medical service in respect of public assistance, poor-law, public hospitals, and private medical charities; (3) the position from the economic point of view of medical officers of health and other sanitary functionaries; (4) the relation of medical practitioners and the judicial authorities; (5) the utilization in times of war of the services of medical men whose period of military service has expired. Then comes the relation of medical practitioners to large bodies which do not depend on the State, such as insurance companies, railway and maritime companies, large industrial enterprises, mines, mills, factories, etc., provident and benefit societies, and private charities. The second section will discuss the relations of the medical practitioner with his patients, his relations with dispensing chemists, with trained nurses, midwives, manufacturers of surgical appliances, and others. In this section, also, the question of medical practice by unqualified persons will be debated. The third section will be devoted to the relations of medical practitioners with their colleagues—consultations, clinics and medical institutions, locum tenens, the sale of practices, the relations between medical practitioners of different nationalities, professional medical societies, the formation of medical unions or syndicates to defend the economic interests of the profession, and other societies of medical men. The fourth section is to discuss all that relates to mutual aid and assistance among members of the profession, such as insurance in case of illness, a fund for old-age pensions, and help for the widows and children of medical men. The general secretary of the committee on organization of the congress is Dr. Jules Glover, Rue du Faubourg Poissonnière, 37, Paris, to whom all inquiries should be addressed. The president of the committee is Dr. L. Lereboullet, and the treasurer M. Pierre Masson, Boulevard St. Germain, 120.

**The Army Hospital Corps.**—According to a recent general order, the hospital corps detachment allowed a regiment serving in divisions and departments of the insular possessions and dependencies of the United States is fixed at one hospital steward, three acting hospital stewards, and twelve privates of the hospital corps. The officers commanding the division of Cuba, the department of Porto Rico, the department of the Pacific and the troops in Hawaii are charged with the full control of the transfer from the line, enlistment, re-enlistment, and discharge of members of the hospital corps of the commands, and with the detail of acting hospital stewards.

**A New Infectious Disease of Dogs.**—Dr. Johannes Horowitz writes to the New York *Times* from Vienna that for a year past an extraordinary number of dogs have been taken ill and died in different German towns under very striking conditions. At first it was believed to be due to malicious poisoning, but it was soon discovered to be a malignant epidemic. From the observations of Herr Kurtz, veterinary surgeon at Stuttgart, it appears that the disease, which everywhere assumes the form of an epidemic, is an infectious disease of the nature of gastric catarrh, with bleeding from the mucous membrane of the mouth. At Stuttgart at first seventy per cent. of the cases ended fatally, which number afterward fell to forty per cent. The epidemic is now nearly over there; but as yet the cause of the disease is unknown. Animals which have once had the complaint and recovered seem to acquire immunity, for no case has been observed in which a dog has been attacked twice.

**Revision of the Pharmacopœia.**—In accordance with resolutions passed at the National Convention for Revision of the United States Pharmacopœia held in Washington in 1890, a general convention for the revision of the pharmacopœia will be held in Washington, beginning on the first Wednesday in May, 1900. It is requested that the several bodies represented in the conventions of 1880 and 1890, and also such other incorporated State medical and pharmaceutical associations, and incorporated colleges of medicine and pharmacy, as shall have been in continuous operations for at least five years, shall each elect delegates, not exceeding three in number; and that the surgeon-general of the army, the surgeon-general of the navy, and the surgeon-general of the marine-hospital service shall appoint, each, not exceeding three medical officers to attend the convention. It is desired that the several medical and pharmaceutical bodies, and the medical departments of the army, navy, and marine-hospital service shall transmit to Dr. H. C. Wood, of the University of Pennsylvania, the names and residences of their delegates, so soon as they shall have been appointed. It is also requested that the several medical and pharmaceutical bodies concerned, as well as the medical departments of the army, navy, and marine-hospital service, shall submit the present pharmacopœia to a careful revision, and that their delegates shall transmit the result of their labors to Dr. Frederick A. Castle, secretary of the committee of revision and publication of the United States Pharmacopœia, 51 West Fifty-eighth Street, New York City, at least three months before the date fixed for the meeting of the convention.

**The Ameer of Afghanistan** has secured the services of a Russian woman, Miss Termoshova, a graduate of the University of St. Petersburg, as physician to his wives and children. The former medical attendant in the harem was an Englishwoman.

**Increased Hospital Accommodation in Paris.**—A proposal for a considerable extension of the hospital accommodation of Paris is now before the municipal council. To carry this scheme into effect it is estimated that a sum of 72,000,000 francs (£2,880,000) will be required. With this fund 2,810 additional beds could be provided.

**A Woman's University in Moscow.**—Mr. Astrakoff, a wealthy Russian engineer, who recently died, left 1,000,000 rubles ($500,000) toward the foundation of a university for women in Moscow. The university is to comprise a mathematical, a scientific, and a medical faculty. The municipal council of Moscow has voted an annual grant of 3,000 rubles to the institution.

**Regulation of Massage in Hungary.**—The Hungarian minister of the interior has issued stringent regulations for the control of massage establishments, etc. Massage treatment in diseases of the sexual and abdominal organs and of the eye may be carried out only by qualified medical men. In all other cases the operator must have the advice and supervision of a qualified medical man. Transgression of these rules is a misdemeanor punishable, if free from aggravating circumstances, by imprisonment up to fifteen days and a fine not exceeding 100 gulden.—*Medical Magazine.*

**The Spread of Consumption in Indiana.**—Governor Mount, of Indiana, has evidently a tender regard for criminals and a ferocious hatred of honest people outside of jail. He has recently announced his intention to pardon or parole all prisoners in the penitentiary who have tuberculosis. His alleged reason for so doing is that the disease is contagious, and he fears the other inmates will catch it. So he frees the spreader of contagion from the one place where he is no longer a source of danger to any one, and sends him out into the world to infect others. Some one should suggest to this crayfish sanitarian to keep the consumptives in jail and free the well prisoners. That would be jollier all around, and would boom the business of the courts, though it might not be so good for the doctors and undertakers.

**A Question of the Physician's Veracity.**—So many physicians' certificates of ill health have been presented of late by jurors who seek to be excused from duty on the plea that they are unable to endure the hardship of sitting in a jury-box, that the supreme-court justices are growing skeptical. They say that the simple certificate in writing over a physician's signature is worthless unless the document bears the jurat of a notary public or commissioner of deeds, showing

that the doctor has fortified his diagnosis of jury illness by an oath. One of the justices is reported to have declared that he will not accept the illness of a juror as an excuse for non-attendance unless the physician appears in person before him for examination as to the condition of the patient.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending July 1, 1899. June 23d.—Assistant Surgeon W. L. Bell detached from the naval hospital, Mare Island, Cal., and ordered to the *Philadelphia*. Assistant Surgeon H. E. Odell detached from the *Philadelphia* and ordered to the naval hospital, Mare Island, Cal. June 28th.—Assistant Surgeon F. M. Bogan ordered to additional duty at the Boston navy yard. Passed Assistant Surgeon R. G. Brodrick ordered to Washington, D. C., July 6th, for examination for retirement, and then home and to wait orders. June 24th.—Passed Assistant Surgeon J. C. Rosenbleuth detached from the *Buffalo*, when put out of commission, and ordered to the *Vermont* immediately.

**An Austrian Ambulance Ship.**—The example given by the United States during the Spanish-American war of fitting out an ambulance ship under the Red Cross regulations has been followed, we learn from the *British Medical Journal*, in Austria. The enterprise, which is due to private initiative, is intended to commemorate the jubilee of the Emperor Francis Joseph. At the express desire of the Emperor the vessel has been named the *Graf Falkenhayn*, after the first President of the Austrian Red Cross Society. The association has been entrusted with the care of the ambulance ship by the donor, Baron von Reinelt, who has also devoted a sum of 50,000 florins to its maintenance in times of peace. The new steamer, which has an estimated speed of nine knots, has an isolated wing for infectious cases, and two bathrooms, and is provided with all modern hygienic requirements. Its equipment, which is now complete, includes four lifeboats and two disjointable rafts. The *Graf Falkenhayn* will for the present be stationed at Trieste, where she will be placed in charge of a retired officer of the Austrian Lloyd Company. The Austrian Red Cross Society is the first institution of the kind in Europe which possesses a permanent naval ambulance.

**The British Medical Association** will hold its sixty-seventh annual meeting at Portsmouth on Tuesday, Wednesday, Thursday, and Friday, August 1, 2, 3, and 4, 1899. The president-elect is Dr. John Ward Cousins. The address in medicine will be delivered by Sir Richard Douglas Powell, and that in surgery by Dr. Alexander Ogston. The following are the subjects announced for set discussions in the several sections: Medicine: (1) "The Medical Tests Required at Present for Admission to the Public Services"; (2) "The Preventive and Remedial Treatment of Tuberculosis." Surgery: (1) "The Diagnosis and Treatment of Gunshot Wounds of the Abdomen"; (2) "The Prevention and Treatment of Syphilis in the Navy and Army." Obstetrics and gynæcology: (1) "The Treatment of Fever Following Delivery, with Special Reference to Serum-therapy"; (2) "The Natural Menopause Compared with (*a*) the Menopause Produced by Removal of the Uterine Appendages; and (*b*) the Menopause Produced by Removal of the Uterus without Removal of the Appendages." Tropical diseases: (1) "Psilosis or Sprue; Its Relations (Etiological and Pathological) to Other Forms of Tropical Diarrhœa, and its Treatment"; (2) "On Thermic Fever (So-called Siriasis), with Special Reference to its Alleged Microbic Causation"; (3) "The Agency of Insects in Spreading Infections."

**Christian Science and the Law.**—We cannot see that there is any flaw in the argument from the New York *Times*, that "if we make laws to protect the public against spurious butter, why not make or enforce laws against spurious doctors? A quack is not less dangerous because he takes the name of the Saviour to hide his ignorance and cover his homicides." Certainly a man is not allowed to sell gunpowder, dynamite, and other explosives without a license; why should he, as a Christian or as a scientist, be permitted to distribute infection gratuitously?—*Buffalo Commercial.*

**Sir William Henry Flower,** of London, died on July 2d. He was born at Stratford-on-Avon in 1831 and was elected a fellow of the Royal College of Surgeons in 1857. At the time of his death he was president of the Zoological Society.

**Decreased Death Rate in New York State.**—The bulletin of the State board of health says that the number of deaths reported during May, 1899, was 9,556, the average for the ten years past. It was 200 less than that of last May and 850 less than that of April of this year, the average daily mortality having been reduced from 346 to 308. The death rate now is 16. The decrease from last month is in acute respiratory diseases, from which there were 500 fewer deaths. There were also 50 fewer deaths from zymotic diseases.

**Obituary Notes.**—Dr. George Thomas Dutcher, of Far Rockaway, New York, died in Pasadena, Cal., June 23, 1899, aged thirty years. He was a graduate of the College of Physicians and Surgeons of New York of the class of 1894. Soon after his graduation he went to California for his health, where he has since lived. He was a young man of superior attainments and character and remarkably fine personal qualities. —Dr. Francis E. Noble, of Jersey City, died on June 29th of broncho-pneumonia, at the age of seventy-five years. He was born in New York City and was graduated in medicine from the medical department of the Western Reserve University in 1851. After graduation he settled in Jersey City and had practised there ever since. He left a widow, two daughters, and one son.—Dr. Paul Clendenin, captain and surgeon, United States army, died of yellow fever at Santiago on July 4th. He entered the army as assistant surgeon from Illinois in 1886, and was appointed captain in 1891. During the war he held the rank of major and brigade surgeon of volunteers. He was in charge of the army hospital at Santiago.

# Reviews and Notices.

Die multiple Fettgewebesnekrose. Klinische und experimentelle Studien. Von Dr. Arthur Katz und Dr. F. Winkler, Assistenten in der allgemeinen Poliklinik in Wien. Berlin: S. Karger. 1899.

The obscurity that still exists regarding a very large part of the pathology of the pancreas makes the results of every investigation tending to the solution of some of the problems involved, of much interest. By a careful study of the published reports of cases and further animal experimentation, the authors, if not fully clearing up the matter, have made an appreciable advance toward the understanding of fat necrosis that so often seems directly referable to lesions of the pancreas. Significant facts are, that it was found possible to produce abdominal fat necrosis by the application of ligatures to the pancreas; that the lesion was attended by hyperleucocytosis; and that distinct diminution in size of the spleen was usually observable.

Handbook of Hygiene and Sanitary Science. By George Wilson, M.A., M.D., LL.D. Edin., F.R.S. Edin., D.P.H. Camb., Medical Officer of Health for the Mid-Warwickshire Combined District. Eighth edition. London: J. and A. Churchill. Philadelphia: P. Blakiston, Son & Co. 1898.

We have had occasion to commend this volume in noticing its former editions. With its increasing size has gone, in large measure, increasing value, but also at the same time the author has permitted a certain amount of dry rot to remain. In the chapters on infectious diseases he shows some haziness on matters now pretty clearly understood, and in other portions of the book some antiquated notions have not been dressed in more modern garb. Withal, however, we believe the work to be the best of the small manuals on hygiene.

The Serum Diagnosis of Disease. By Richard C. Cabot, M.D., Physician to the Out-Patients, Massachusetts General Hospital. New York: William Wood & Co. 1899.

If the experiences of the recent war have demonstrated anything, they have certainly brought into prominence two facts. One is, that the microscopical examination of the blood is an extremely important and reliable means of determining the presence of malaria, and the other that the serum reaction is an equally important aid in the diagnosis of typhoid. This present essay, or compilation, is a result of the author's investigations in Cuba, and is a timely and interesting contribution to our knowledge of the serum test (Widal) in typhoid. Serum reactions in other diseases are also briefly touched upon, and a complete bibliography is appended. The work is of value, and is well gotten up from the standpoint of the bookmaker's art.

Die Wanderniere. Ein Beitrag zur Pathologie des intra-abdominalen Gleichgewichts. Von Dr. Med. M. Wolkow und S. N. Delitzin, Privat-Docenten an der Kaiserlichen militar-medicinischen Akademie in St. Petersburg. Mit Abbildungen im Text und 35 Lithographischen Tafeln. Berlin: Hirschwald. 1899.

The importance which is of late being attached to the pathology and causation of the various forms of movable and dislocated kidney makes this an especially welcome contribution to our knowledge of the subject. The work of these two authors embraces the results of experiments covering a period of four years and performed on one hundred male and female cadavers. The conclusion reached is that the active physiological factor which retains the kidneys in their normal position is not to be found in their peritoneal ligaments, nor in the subperitoneal fascial ligaments, nor in the vessels, nor in the capsule of perirenal fat, but in the general conditions of normal intra-abdominal equilibrium. Circumstances liable to produce a disturbance of this state are, relaxation of the anterior abdominal wall, pendulous abdomen, ascites, sudden evacuation of the abdominal cavity as in parturition, prolapses, hernias, enteroptoses, alterations in the weight of individual organs, etc.

As a second passive or anatomical factor is to be regarded some peculiarity of conformation of that portion of the posterior abdominal wall in relation to the kidney and along which a dislocation causes it to glide. By means of plaster casts it was possible to demonstrate that the "paravertebral niches" which form the nidus of the organ are subject to individual variations, and that abnormality of these has a direct relationship to the occurrence of movable kidney. The subject is treated at great length and with much minute attention, and the book deserves thoughtful attention from all interested.

Examination of Water (Chemical and Bacteriological). By William P. Mason, Professor of Chemistry, Rensselear Polytechnic Institute. Third edition. New York: John Wiley & Sons. 1899.

This book is for the undergraduate student. It contains no information for the actual worker in water supplies, but is a convenient, handy manual for class-room work. In the author's introduction, he aptly says that a water analysis is not in a true sense an analysis at all, *i.e.*, a chemical analysis. It usually consists of a series of unintelligible figures—unintelligible to the laity, and, it must be confessed, in large measure to chemists also. The author, in a mild way, suggests that the examiner should inspect the source of a water supply before pronouncing on its potability. When it is borne in mind that one of the foremost authorities of Germany, Flügge, maintains that the inspection of the sources of a water supply is the main requisite, and worth more than any other means of examination, the author of this modest manual, and others in the same line, should lay more stress upon this, the essential point, and less on the chemical analysis. A brief account of the bacteriological means of examining water is included, but it is too brief to be of much service. No mention is made in the work of the microscopical examinations of water, which have of late years become so important.

Respiratory Exercises in the Treatment of Disease, Notably of the Heart, Lungs, Nervous and Digestive Systems. By Harry Campbell, M.D., B.S. Lond., Fellow of the Royal College of Physicians, London, Physician to the Northwest London Hospital and to the Hospital for Diseases of the Nervous System, Walbeck Street. New York: William Wood & Co. 1899.

The author adopts as his thesis that marked effects on the animal organism may be produced by modifying the respiratory movements, and, in accordance with this, has presented a very serviceable handbook, describing what the changes are and how they may be made of service in the treatment of disease. The methods so commonly employed at Bad Nauheim are of the same class as those treated of in this volume, but, as the author has pointed out, his deductions are more in the line of applied physiology than are those laid down at this well-known health resort.

The book, of about two hundred pages, is made up of twenty-six chapters. The first ten are devoted to the anatomical and physiological factors that are concerned in the acts of normal and forced breathing. The following chapters discuss at varying lengths the action of respiration on the various organs of the body, and the therapeutic applications that may be made of this process in diseased conditions. The work fills a gap in hygienic literature, and will be especially welcome to those trainers of our youth who wisely consider the importance of the respiratory function.

An American Text-Book of Diseases of the Eye, Ear, Nose, and Throat. Edited by G. E. De Schweinitz, A.M., M.D., Professor of Ophthalmology in the Jefferson Medical College, Philadelphia; Consulting Ophthalmologist to the Philadelphia Polyclinic; Ophthalmic Surgeon to the Philadelphia Hospital and to the Orthopedic Hospital and Infirmary for Nervous Diseases; and B. Alexander Randall, M.A., M.D., Ph.D., Clinical Professor of Diseases of the Ear in the University of Pennsylvania; Professor of Diseases of the Ear in the Philadelphia Polyclinic; Ophthalmic and Aural Surgeon to the Methodist and Children's Hospitals, Philadelphia. Illustrated with 766 engravings, 59 of them in colors. Pages, 1,251. Philadelphia: W. B. Saunders. 1899.

This volume makes a valuable addition to the series of "American Text-Books," and is designed for students, general practitioners, and specialists. In all, there are sixty authors represented in its compilation, each one being selected with special reference to work which he has done on the sub-

ject treated, this naturally causing such a book to express conflicting opinions. The editors have, however, supplied cross references where such discrepancies exist. Dr. de Schweinitz has assumed full editorial responsibility for the articles on ophthalmology, and Dr. Randall for the otological and laryngological sections. As the preface states, in the portion of the work devoted to the eye, its embryology, anatomy, histology, physiology, diseases, and injuries are discussed in twenty-four sections by twenty-four authors, its operative surgery in seven sections by as many authors; while certain practical details in the examination for color-blindness among railroad employés, etc., receive attention in an appendix containing five sections. In the portion devoted to the ear, its anatomy, physiology, diseases, and injuries are discussed in thirteen sections by fourteen authors, while diseases of the nose and throat are described in twenty sections by nineteen authors. Among its special articles we note "The Roentgen Rays in Ophthalmic Surgery," "The Practice of Ophthalmic Operations on Animals' Eyes," and an interesting article on "The Micro-organisms in Ocular Diseases." The volume is well arranged, and well printed; its illustrations are excellent, and the practical side of its teachings is especially complete.

TRANSACTIONS OF THE AMERICAN OTOLOGICAL SOCIETY. Thirty-first Annual Meeting, Pequot House, New London, Conn. Vol. VII., Part I.

BESIDES the list of members, this volume contains numerous interesting articles with the subsequent discussion, and an alphabetical index of otological bibliography from June 1, 1897, to June 1, 1898. To those interested in otology, this volume is certainly very valuable.

TRANSACTIONS OF THE LUZERNE COUNTY MEDICAL SOCIETY, for the Year Ending December 31, 1898. Vol. VI.

THIS volume contains two hundred and seventeen pages, embracing twenty-one articles on diverse subjects. Additional interest is given by the publication of the discussion on the various papers, thus rendering the articles doubly interesting.

SYPHILIS. Von DR. ISIDOR NEUMANN, O. ö. Professor der Dermatologie und Syphilis an der Universitat Wien. Zweite Auflage. Wien: Alfred Holder. 1899.

THIS second edition of Neumann's carefully written and rather exhaustive treatise on syphilology occupies eight hundred and fifty pages, illustrated with sixty wood-cuts. The first twenty-nine pages are given to the history of syphilis; then follows its distribution. Then, after a special chapter devoted to venereal ulcer and venereal bubo, begins syphilis proper, with a consideration of the primary sclerosis, and from this point are traced all the phases and forms which the affection may assume through the brain and nervous system, and the hereditary forms. The author's long and wide experience as student, observer, and teacher of this branch in a university whose material is of world-wide fame makes his writings of special value. The present edition shows evidence of having been carefully gone over before publication, and some condensation has been made. The treatise constitutes volume xxiii. of Nothnagel's work on Special Pathology and Therapy.

DIE KRANKHEITEN DER MUNDHÖHLE, DES RACHENS UND DES KEHLKOPFES. MIT EINSCHLUSS DER UNTERSUCHUNGS- UND BEHANDLUNGSMETHODEN. Für praktische Aerzte und Studierende. Von DR. ALBERT ROSENBERG, in Berlin. Zweite Auflage, mit 180 Abbildungen im Text. Berlin: S. Karger. 1899.

THIS excellent treatise has been increased in volume by almost a quarter in its present second edition. Sixty-six pages are devoted to diseases of the mouth, one hundred and thirty-eight to those of the throat, and one hundred and ninety-three to the larynx. The author's work has already been much praised for its clearness and conciseness, as well as for its pedagogical value, but the practitioner will also find it most valuable as a reference book, as even the rarer conditions of disease are described and the therapy and treatment of the more common troubles more elaborately discussed. A large number of excellent illustrations fully elucidate the anatomy and pathology as well as the technique and methods of examination, and for readers of German the book is to be warmly commended.

## Therapeutic Hints.

**Lupus.**—

℞ Salicylic acid ..... ʒ iiss.
Creosote ..... ʒ v.
Simple cerate ..... ʒ iiiss.
White wax ..... gr. lxxv.
M. S. Apply externally.

—UNNA.

**Coccygodynia.**—

℞ Ext. belladonnæ ..... gr. ¼
Ext. hyoscyami,
Iodoformi ..... āā gr. ¾
Olei theobromæ ..... gr. xx.
M. ft. suppos. S. Employ at bed-time.

—WHITLA.

**Intestinal Colic.**—

℞ Bismuthi subnit. ..... ʒ ss.
Pulv. cinnamomi ..... ʒ i.
Ext. nucis vomicæ ..... gr. i.
Sacch. alb. ..... ʒ ij.
M. ft. pulv. S. ʒ i. before diuner.

—*Med. Sum.*

**Intercostal Neuralgia.**—

℞ Chloralis,
Camphoræ,
Mentholis ..... āā ʒ i.
M. S. Apply with brush.

—SOLIS-COHEN.

**Coryza.**—

℞ Menthol,
Camphor ..... āā gr. v.
Albolene ..... ʒ ij.
M. S. Use with atomizer every two hours.

—*Prescription.*

**Pruritus Ani.**—

℞ Sodium hyposulphite ..... 30
Carbolic acid ..... 5
Glycerin ..... 20
Water ..... 450
M. S. Apply wet compresses.

—PENZOLD.

**Sea-Sickness.**—

℞ Menthol ..... gr. iss.
Cocaine hydrochlorate ..... gr. iij.
Alcohol ..... ʒ ij.
Simple syrup ..... ʒ i.
M. S. ʒ i. every half-hour.

—A. MOREL-LAVALLÉE.

**Menopause.**—

℞ Ammonii bromidi ..... ʒ ij.
Sodii bromidi ..... ʒ ss
Spir. ammon. aromat ..... ʒ vi.
Aquæ camphoræ ..... q.s. ad ʒ vi.
M. S. Tablespoonful every four hours.

—PARVIN.

**Blennorrhagic Urethritis.**—

℞ Methylene blue ..... 0.06–0.12
Ol. santali,
Ol. copaibæ ..... āā 18
Ol. cinnamomi ..... gtt. i.
M. For one capsule. S. Give one such three times a day.

—HORWITZ.

**Syphilis.**—

℞ Hydrargyri di-iodati ..... 1
Potassii iodidi ..... 10
Syrupi simplicis ..... 200
M. S. Teaspoonful to tablespoonful at dose.

**Yellow Oxide Ointment,** which will keep without decomposing:

℞ Hydrarg. oxidi flav. (recent) ..... 0.01–0.05
Lanolini.
Aquæ destill ..... āā 2
Petrolati ..... q.s. ad 10
M. Put into black glass.

**Pertussis** may be limited to a week by local use of formalin in dilute solution. It causes emesis, which further tends to dislodge germs.—H. S. OLIPHANT, *New York Medical Journal*, March 4, 1899.

**Tapeworm.**—After the bowels have been moved by oil or salts, give:

℞ Spir. chloroformi ..... ʒ ij.
Ess. terebinth. rect.,
Ext. filicis ether.....āā ʒ i.
Glycerini ..... ʒ iv.
M. S. Teaspoonful every hour.

**Tonsillitis.**—

℞ Sodii benzoat..... ʒ i.–iv.
Glycerini,
Elix. calisayæ.....āā ʒ i
M. S. A teaspoonful every one or two hours.

—Stevens.

**Correction of the Taste of Unpalatable Drugs.**—In his "Pocket Formulary of Diseases of Children" Dr. L. Freyberger has devoted considerable attention to the important question of how to disguise the taste of nauseous drugs. The following list is given:

Acetanelid—gr. i. is disguised by gr. iii. of white sugar or gr. ij. of elæosaccharum menthæ piperitæ.
Aconite—♏ i. of tincture is disguised by ♏ v. of elixir simplex.
Ætheris Nitrosi Spir.—♏ v. by ʒ i. of sugar water or aqua carui.
Aloin—gr. ¼ by ♏ x. of extr. glycyrrhizæ liquidum.
Ammonii Acetatis Liq.—♏ v. by ʒ i. aq. camphoræ, menth. pip., or mist. amygdalæ, milk, and boiling water.
Ammonii Bromidum—gr. i. by ♏ v. syr. aurantii.
Ammonii Carbonas—gr. i. by ♏ v. syr. aurantii or tolu.
Belladonnæ Extr.—gr. ⅛ by ♏ ii. spir. chloroformi or ♏ v. syr. aurantii.
Belladonnæ Tinct.—♏ ii. by ♏ ii. syr. aurantii.
Caffeinæ Citras—gr. i. by ♏ xxx. syr. limonis.
Calomel—gr. i. by gr. iv. saccharum lactis.
Camphora—gr. ⅛ by gr. iii. pulv. cinnamomi comp. or ʒ i. aq. cinnamomi.
Cascaræ Sagrad. Extr. Fl.—♏ x. by ♏ v. syr. zingiberis and ext. liquiritiæ fld.
Chloral Hydras—gr. i. by ♏ v. syr. aurantii or pruni virginianæ with ʒ i. aq. cinnamomi.
Copaiba—♏ v. by ʒ ii. mistura amygdalæ.
Creosotum cannot be effectually disguised—♏ i. in ʒ i. mist. amygdalæ.
Cupri Sulphas—gr. i. by ʒ ii. syr. simplicis.
Digitalis Tinct.—♏ i. by ♏ v. syr. aurantii.
Ferri Perchloridi Tinct.—♏ i. by ♏ v. syr. aurantii or glycerin.
Filicis Maris Extr. Liq.—♏ xx. by ʒ i. syr. cinnamomi.
Guaiacolum—gr. i. by ʒ ii. of sherry wine.
Ipecacuanhæ Pulv. Comp.—gr. ss. by gr. ss. pulv. cinnamomi and gr. i. sugar.
Morrhuæ Oleum—♏ x. somewhat disguised by ♏ i. essence of almonds and lemon, or by ♏ ss. ol. menth. pip.
Nucis Vomicæ Tinct.—♏ ss. by ♏ x. syr. aurantii.
Pepsinum—gr. i. by ♏ v. syr. aurantii.
Phosphoricum Acid. Dil.—♏ i. by ♏ v. syr. rubi idæi.
Phosphorus—♏ i. of ol. limonis to ounce of mixture makes it more palatable.
Potassii Arsenitis Liq.—♏ i. disguised by ʒ i. aq. cinnamomi or ♏ v. syr. tolutani.
Potassii Acetas—gr. iii. by ♏ xv. syr. rubi idæi.
Potassii Bromidum—gr. iii. by ♏ xv. syr. aurantii.
Potassii Iodidum—gr. i. by ʒ ss. aq. menth. pip.
Quininæ Hydrochlor.—gr. ss. by ♏ xx. syr. aurantii.
Ricini Oleum—♏ v. by ♏ iii. syr. zingiberis and ʒ i. aq. menth. pip
Sodii Salicylas—gr. iii. by ♏ v. syr. simplicis and ʒ i. aq. cinnamomi.
Strychninæ Hydrochlor. Liq.—♏ i. by ♏ x. syr. aurantii or zingiberis or ♏ xv. extr. glycyrrh. liq.
Tannicum Acidum—gr. ½ by ♏ v. syr. zingiberis

**In Tabes to Stimulate Circulation.**—

℞ Ammon chlor ..... ʒ iv.
Glycerini..... ʒ i.
Tinct. capsic..... ʒ ss.
Aquæ menth. pip.....q.s. ad ʒ xij.
M Rub on the body daily for twenty minutes with massage.

—Pearce.

**Unguentum Hydrargyri by the Mouth.**—

℞ Ung. hydrargyri cinerei ..... gr. lxss.
Pulv. glycyrrhiz..... gr. lxxv.
Glycerini..... gtt. v.
Mucilaginis ..... q.s.
Ut ft. pil. No. lx. S. Two pills twice daily.

—Silberstein.

**Dyspepsia with Flatulence.**—

℞ Tincture of gentian,
Tincture of valerian.
Tincture of nux vomica .....āā ʒ i.
Chloroform..... gtt. xx.–xl.
M. S Ten to twenty drops in water before meals.

**Blennorrhagia.**

℞ Menthol ..... gr. ss.
Salicylic acid ..... gr. ij.
Phenic acid,
Lactic acid,
Essence of eucalyptus.
Salicylate of methyl.....aā gr. iv.
Resorcin ..... gr. x.
Water ..... ʒ iv.

The above formula, taken from *The Medical Press* of March 15th, is not intended to supply a distinct drug for each gonococcus encountered, but it is thought that a mixture of several agents will prove more efficacious than a strong dose of a single one. The quantity to be injected twice a day is one-half syringeful.

**Rheumatic Affections.**—Phenacetin either in the form of:

℞ Phenacetin ..... 5 parts.
Lanolin..... 20 "
Ol. olivæ..... q.s.
Fiat ung.

Or as compress—

℞ Phenacetin ..... 5 parts.
Alcohol rect..... 1 part.
To be applied as hot as possible.

—*Klin.-therap. Wochenschr.*, 1898, p. 186.

**Blennorrhagic Myositis.**—Apply locally as soon as the acute period has passed:

℞ Guaiacol oil,
Oil of sweet almonds ..... p. æ.

In the beginning envelop the limb in boric-acid solution heated to about 35° C. Cover with impermeable tissue, cotton, and fix with a bandage.—Braquehaye and Servel.

**Atonic Dyspepsia.**—

℞ Sodii bicarbonatis..... gr. xv.
Tinct. nucis vomicæ ..... ♏ xv.
Tinct. calumbæ ..... ʒ ss.
Spir. ammon. aromat ..... ʒ ss.
Infus. aurantii comp .....ad ʒ i.
M. f haus. S. As a dose, three times daily half an hour before meals

—Burney Yeo.

**Lichen Islandicus in Bright's Disease.**—Dr. Morosov (*La Semaine médicale*, No. 58, 1899) recommends a decoction of lichen islandicus 4 to 8 in 100 as a good diuretic in morbus Brightii. He has frequently seen an increased urinary excretion, diminution of albumin, and disappearance of œdema follow its use. The patient should be placed on a milk diet.

**Influenza.**—Half an ounce of a decoction of cinnamon every half-hour for two hours, then every hour until the temperature falls to normal. The decoction is prepared by slowly boiling a pound of cinnamon in vacuo with a sufficiency of water till the fluid is reduced to a pint and a quarter. Tabloids may be substituted.—J. C. Ross.

**Digitalis in Cardiac Disease.**—Research would seem to prove that the prolonged use of digitalis is capable of producing cardiac hypertrophy in the normal heart: and if this is the case, it is fair to assume that when the drug is given to a man suffering with valvular disease with deficient compensation, it must aid materially in inducing compensatory hypertrophy, in addition to any immediate stimulant action which it may exercise in the circulatory apparatus.—Hare.

# Society Reports.

## ONTARIO MEDICAL ASSOCIATION.

*Nineteenth Annual Meeting, Held in Toronto, June 13 and 14, 1899.*

W. J. Gibson, M.D., of Belleville, President, in the Chair.

*First Day—Tuesday, June 13th.*

**A Case of Muscular Dystrophy.**—Dr. Ingersoll Olmsted, of Hamilton, reported this case. The subject was a young married man, twenty-five years of age, who had come to the doctor complaining of wasting of muscles and inability to work. His family history showed that other members thereof (though not either parent) had been afflicted with the same trouble. The patient was presented to and examined by the members of the association, and the peculiarity of his gait and movements noted, especially interesting being his manner of assuming the erect posture from a prone position. Wasting was most marked in the region of the scapulæ, deltoids, biceps, forearm and thigh muscles, while those of the calves and hands were moderately well developed. Winging of the scapulæ was especially well marked.

Dr. McPhedran stated that he had examined the case with very much interest. It was an orthodox case of this kind, but presented one or two phases of unusual character especially the preservation of the trunk muscles. He nought there must be some degeneration of nerve fibres present in these cases.

Dr. Geikie thought that as we came to know more and more of this disease, destructive changes would be found to be existing in the nerve centres.

Dr. Olmsted said, with regard to Dr. Geikie's remarks, that he thought there was no question that extensive atrophy took place without any involvement of the central nervous system.

**Relapse in Typhoid Fever.**—Dr. J. C. Wilson, of Philadelphia, read a paper on this subject. He exhibited a number of temperature charts, and said that especial attention should be paid to the condition of the gall bladder as a causative factor in producing these relapses. He took this as his "working hypothesis," and proceeded to demonstrate the occurrence of a relapse with the renewed physical movements of the patient, the beginning of the administration of the more solid forms of food, the consequent peristalsis thus produced in the gall bladder and the subsequent discharge of the accumulated contents of this cyst, containing large quantities of the bacillus typhosus, into the intestine, thus producing the reinfection and the relapse. This, he thought, must be due to intrinsic and not to extrinsic infection. Dr. Wilson then spoke for some time on immunity, and concluded by saying that thus we had a "working hypothesis" to explain relapse, which might be set forth in these terms: intrinsic reinfection from the gall bladder at a time when the intestines were stimulated by larger meals of a different character, an immunity not yet complete, and reinfection at once without a period of incubation. He perfectly understood that the change in blood serum which underlay the Widal test was not a process of immunity but a process due to the infection. He closed his paper by saying that the histological changes taking place in the solids and fluids of the body, bringing about immunity, were also gradual, and if the "working hypothesis" stood at all, it demanded that complete immunity should be established in the primary attack; otherwise intrinsic reinfection, which gave rise to the relapse, could not possibly occur.

Dr. McPhedran thought Dr. Wilson's definition of relapse a good one, and that he drew a very clear picture of it. We knew that some of the cases of typhoid might be abortive, and he saw no reason why relapses also should not be abortive. The question of the gall bladder as being the source of the infection in these relapses was a very important one, because of the suddenness of the outbreaks of symptoms. He thought the relapse might be due more directly to the toxins in the bile.

Dr. J. L. Davison quoted Fagge referring to cases in Guy's Hospital in which death had occurred from the sequelæ of typhoid fever weeks after convalescence had been established, and in which, on post-mortem examination, Peyer's patches were found still infected or still in a condition which showed evidences of the bacillus. In many cases the disease smouldered along for weeks. While Dr. Wilson's hypothesis of the gall bladder was a reasonable one, it hardly explained why we should have relapses after thirty days and later. There must be other storehouses for the retention of the specific germs. The question of the number of relapses was a very interesting one. While Dr. Wilson stated he had seen as many as seven in a six months' illness, the largest number the speaker had seen in any one case was three. He instanced a case of recovery after perforation. The question of immunity was an interesting one in typhoid fever. From recent researches it appeared that there were two immunity substances, one which produced an antitoxin and destroyed the action of the toxin in the body, and thus served to keep the patient alive; and the other which was bactericidal in its action. It appeared that we must have both of these in order that a patient may recover from the disease. It was this bactericidal element which had a large part to play in the destruction of the germ itself.

Dr. Thistle asked why we went to the gall bladder when the bacilli were in the intestinal contents.

Dr. Wilson in reply said that the infection came from the gall bladder because the toxin was accumulated in a great mass in a hollow viscus, which under physiological conditions of the low diet might remain there; but when the patient began to take solid food at longer intervals the gall bladder was suddenly stimulated to empty itself. Under the condition of feeding small amounts of fluid alone, the gall bladder was not stimulated to push out its contents.

**President's Address.**—Dr. W. J. Gibson, of Belleville, Ontario, expressed his thanks for the honor conferred on him in having been made president of the association. In regard to serum therapy, it was a matter of congratulation to the profession to know that so many able workers were in the field. He instanced tuberculosis, and stated that the whole world was on the alert to discover a cure for this disease. More attention should be given to personal hygiene and cleanliness. It would be difficult to estimate what good would result from reporting all the cases of tuberculosis to the health officers, but it would be a difficult matter to make isolation in all cases compulsory. He spoke of the number of diseases now treated with antitoxins. No doubt investigators were on the threshold of important discoveries. He then spoke at some length concerning education and medical regisration in the Dominion.

**Tuberculosis.**—Dr. Vincent Y. Bowditch, of Boston, opened the discussion with a paper on "The Sanatorium Treatment of Pulmonary Tuberculosis." It was gratifying, he said, to notice the marked change of opinion in regard to the treatment of tuberculosis in special institutions. Massachusetts had been the first State in America to establish sanatoria. It was important to keep this class of hospitals for incipient cases. He spoke of the educational influence of the

hygienic methods employed in these sanatoria. Open windows, even in cold weather, should be insisted on as a special treatment of the disease. Patients have returned to these sanatoria begging to be taken back because they could not breathe in their own houses. He thought much more could be done for the patients by having them treated nearer home. Much more could be accomplished by treating consumptives in these sanatoria than by treating them in their own homes. Thirty per cent. have been discharged at Sharon as arrested cases. Dr. Bowditch had never used the term "cure," believing that it was unjustifiable until after a lapse of years. The causes of death in these cases were: (1) The advanced condition of the disease on entrance; (2) intercurrence of some other disease; and (3) too early departure from the sanatorium and return home to the unhygienic conditions. As to treatment, experiments were made with the so-called specifics. Oil of peppermint proved at times beneficial. Creosote was found to be beneficial as an aid to digestion. Antiphthisin had no effect. Abundance of fresh air, judicious exercise, pulmonary gymnastics, and calisthenics formed the base of all successful treatment. The results at Sharon meant that sanatoria should be near all the large cities and towns. He congratulated the profession in Ontario upon the establishment of a sanatorium at Gravenhurst, and spoke also of the necessity of having hospitals for the hopelessly sick. We took away the principal source of infection when we removed these from their homes.

**Early Diagnosis and Selection of Cases for Sanatorium Treatment.**—Dr. N. A. Powell said that for ten years he had practised in a part of the province where phthisis was practically unknown. The diagnosis of early phthisis called for what we understand by incipient or early phthisis—the pre-tuberculous stage. In this regard our views had changed materially within recent years. Up to the time of the demonstration of the bacillus, a case was considered early unless there were large growths within the lung, and until gross constitutional symptoms had shown. There was an inherent tendency toward recovery in phthisis when recognized early. This led to the question, How often was phthisis recognized in an early stage, in a stage before physical signs were manifest in the chest and before expectoration had commenced? Very few such cases were recognized. This was in part because medical students crowded the course in surgery and gynæcology, but neglected physical diagnosis. Early diagnosis depended upon close study of family and personal history. There were certain aids to the examination, such as the use of the fluoroscope and the tuberculin test. In regard to the personal make-up of the patient, it was important to estimate weight and height together before we could arrive at anything of importance. The symptoms of early phthisis were uncertain. A man who was in apparently excellent health might have serious pulmonary disease. It was sometimes important to notice any scars of the neck. Cough and early hemorrhage were two symptoms of importance. The patient should be made to cough in the presence of the physician, and any sputum thus gained should be examined. An evening temperature running up two-fifths, three-fifths, or one degree, associated with morning pallor, was one of the most important elements in early diagnosis. Dr. Powell spoke of the physical examination, and said the patient should always be stripped to the skin and examined in a quiet room. If we can get association of relative dulness in the spinous fossæ with the slightest accentuation and conveyance of the whispered voice or any prolonged expiration, it is safer to treat such a patient as being probably tuberculous. In a case presenting progressive loss of weight and loss of physical energy, if one can get a little wavy or cog-wheeled respiration near the lung, it is safest to treat such a patient as being probably tuberculous. Personally, without having much basis to go on, the speaker said that he was afraid to use tuberculin as a test, for fear of lighting up tuberculosis. With the fluoroscope it was easy to recognize excursions upward and downward of the diaphragm during respiration, the average excursion in the adult male being about two and one-half inches. If it was notably lessened on one side it raised strong suspicion of the presence of tubercle.

**Home Treatment and Prevention of Tuberculosis.**—Dr. T. F. MacMahon, of Toronto, read this paper. He first spoke of how we should treat the patient in his own home, and what means we should take to cure the disease and stay its ravages. Without a specific germ there could be no tuberculosis. The main sources of infection were, first, the sputum, and then infected food. Prompt destruction of the sputum would go far toward the removal of the disease. The public generally must be educated to this fact. That the danger from handkerchiefs was a real one was borne out by the facts that washerwomen in health resorts had contracted the disease through washing these handkerchiefs. Very fine drops of saliva might be a source of infection. Intimate association with coughing consumptives was dangerous to nurses in the rooms. Another important instruction was that rooms should be dusted with cloths dampened with a disinfectant solution. Premises occupied by consumptives and vacated should be made fit by the health board for occupation. Association of consumptives with other patients in public hospitals was injurious. Consumptives should not be treated in the ordinary hospitals. There should be systematic inspection of dairies and food supplies. There was also danger of infection from domestic pets, cats, dogs, birds, etc. Patients should have as much open-air exercise as possible. Individuals especially predisposed should receive particular attention. If the family physician would make it his duty to watch for badly formed chests, he could do much. Prompt attention should be paid to anæmic and dyspeptic young women. Every precaution should be taken against "catching cold." The patient should not choose a sedentary occupation. Much out-door life was especially desirable. Cure was altogether a question of instruction. There should be no cough mixtures. The nearer we approached the methods of the sanatoria, the better our results would be. The only method was the open-air treatment. When in the house the patient should occupy the room with the most sunshine. Nothing should be allowed to interfere with the fresh-air treatment. Rest in the open air would improve the digestion.

**Care and Prevention.**—Dr. Charles Sheard spoke of the open-air treatment as the ideal one. This was not the only disease which fresh air benefited. Many cases of bronchitis and bronchiectasis were also benefited thereby. There were a great many cases with cavities in the lungs, and we had to care for those cases as well. We had all seen these patients very recently put side by side in the same ward with a patient with chronic bronchitis, with another with pleurisy, and with another with obscure chest trouble; yet there ought to be better places for the care of these cases. There ought to be separate buildings in connection with our hospitals for those cases which the sanitaria will not admit. As regards the danger of getting tuberculosis from animals, Dr. Sheard quoted Clifford Allbutt, who fed his own family with the meat of tuberculous cattle and yet none of them contracted the disease. The tuberculin test applied to cattle was a very crucial one. In one cow

which responded to the tuberculin test, tuberculosis was limited to one gland alone. Generally it was agreed that tuberculous milk was dangerous according to the stage of the tuberculosis in the animal.

---

SURGICAL SECTION.

*Second Day—Wednesday, June 14th.*

Dr. Wishart, of London, Ontario, was elected chairman of this section.

**Inguinal Hernia.**—Dr. William Oldright presented four patients, in all of whom he had performed the radical cure very recently. He quoted the indications for and against operating in these cases as set forth by Dr. W. B. Coley in Sajous' *Annual*. He thought Halsted's modification of the Bassini method was not an improvement.

**Treatment of Hernia.**—Dr. A. McKay, of Ingersoll, estimated that something like twenty per cent. of the population was ruptured. He exhibited a new truss which he had contrived after a year's experimenting, and stated that in making trials of its efficiency he had selected men who were lifting all sorts of heavy loads and found that it would give the greatest satisfaction. The idea of the truss was to allow of the body motion, a constant wavering of the pad over the ring.

Dr. W. J. Gibson spoke of the difficulty of supplying patients with proper trusses. Dr. McKay's truss was devised to prevent the excoriation of the skin.

**A Peculiar Gynæcological Case.**—Dr. Harrison, of Selkirk, reported this case. The subject was a woman with a large family. Having become pregnant again—two and one-half months—she was advised by a neighbor to produce an abortion, as it was a very easy thing to do, and no trouble arose other than an ordinary monthly sickness. A glass stylet penholder was passed, blunt end foremost, but it slipped from the woman's grasp and was lost. On examination, the speaker could find no rent or tear of any kind, either in the vaginal walls or in the walls of the uterus, even after putting the woman under chloroform. The stylet could not be found. The woman was most positive that it was there, and that it had been passed blunt end foremost. An exploratory abdominal operation was performed, and the stylet was found in the region of the spleen, with the point almost impinging upon the diaphragm where the heart lies on that muscle. The woman recovered with nothing worse than a stitch abscess.

**A Note on Kocher's Method of Radical Cure of Hernia.**—Dr. Primrose gave a very lucid blackboard description of this operation, and showed clearly how the inguinal pouches in the peritoneum were obliterated. As a guide in performing this operation, it was best to introduce a finger into the canal and cut upon the finger. Kocher recommended the silk suture in both operations.

**On Some Points in the Diagnosis of Eye Affections.**—Dr. R. A. Reeve read a very interesting paper with this title. He said this was important for the general practitioner, as patients were continually consulting them with regard to defective sight, or asthenopia, or for actual disease of the eye. It was necessary, in the first place, for the general practitioner to know whether there was any disease present; as to trauma, whether any existed and to what extent the eyeball was damaged; was it in the fundus or in the orbit itself? If a large magnet was brought close to the eye, pain was experienced, owing to the fact that the foreign body was attracted to the magnet and injured the tissues. Then in some cases we had to determine whether there was rupture of the eyeball itself posteriorly. He spoke of rupture by contrecoup, and also of luxation. In the case of foreign bodies we should carefully scrutinize the anterior eye and the conjunctiva. He thought the time had come when the general practitioner should have a fair knowledge of the eye, and be able to apply such knowledge. He should be able to fit the eyes with proper glasses when required. Some persons who could read $\frac{20}{20}$ brought ordinary print close to the eye. Here we should suspect astigmatism. By testing the tension of the eye we obtained a clew to the presence of glaucoma. Another point that should be attended to was the testing of the field of vision, by closing one eye with the hand or using a watch-glass. Diseases of the cornea and conjunctiva were to a large extent now capable of division bacteriologically. We should be on the *qui vive* for tobacco amblyopia in cases of cataract, and it was important to urge men over fifty years old to reduce the quantity of their tobacco.

---

MEDICAL SECTION.

Dr. J. Russell, of Hamilton, was elected chairman of this section.

**Ophthalmology and the General Profession.**—Dr. G. H. Burnham read this paper, the object of which was to bring forward some of the diseases of the eye and also some disturbances associated therewith, which required early recognition in order to be successfully treated. He instanced acute glaucoma, chronic glaucoma, and tobacco poisoning causing dimness of sight. In regard to the subsequent changes produced by an attack of iritis, he did not for these perform iridectomy, but instead of an operation gave his combined form of treatment, viz., mercury and the iodide of potassium internally, and pilocarpine hypodermically. He said his results were in this way much better than those obtained by an operation. In regard to diseases of the tear passage he strongly recommended early treatment. He did not favor the employment of the largest probes and did not probe frequently, as good if not better results could be obtained without the additional suffering which frequent probing was always associated with. He also spoke of eye strain causing so many nervous disorders, as headache, neuralgia, constipation, and St. Vitus' dance, and of the great importance of having the sight tested by an oculist and not by those so-called "doctors of refraction."

Dr. G. S. Ryerson thought that the paper fully met the requirements of the subject. Ophthalmia neonatorum had been, however, omitted. A large percentage of eyes were lost from this cause. Medical men should take great care in cleansing the maternal parts before delivery, and the eyes of infants later. Credé's method greatly reduced the percentage of this disease. One or two drops of a one-per-cent. solution of nitrate of silver should be dropped into the eyes. This is not too strong. In regard to the question of refraction, the term doctor of refraction or doctor of ophthalmology was very misleading. He had tried to legislate against these when he was in the legislature, and had approached the government regarding these titles being used unlawfully. The giving of glasses by laymen to the public had been long done; but these titles were very misleading to the public. The question of refraction was a most difficult and complex one, and how could these men on a few months' training undertake such work and treat such cases?

**The Insanity Plea in Medical Jurisprudence.**—Dr. J. Russell, of Hamilton, read a paper on this subject. He thought the public were beginning to doubt that the law was being properly administered in these cases. The question was of interest to the general practitioner as well as to the psychologist. It behooved every physician to acquire such a general and

even special knowledge of the subject as to be able to acquit himself creditably in the witness box, without bringing personal discredit on himself or the profession.

**Notes of a Case of Torticollis.**—Dr. D. C. Meyers, of Toronto, presented a patient, a married woman, aged thirty-nine years. The trouble came on at the age of twenty-five years, just after the birth of her last child. At that time she was very sensitive as to people looking at her. About three years ago she first noticed that her head would turn voluntarily to the left shoulder, slightly at first, in any position but the recumbent one. She was obliged to keep her hand to her chin to hold her head in position. The right sterno-mastoid was prominent and much hypertrophied. Her neurasthenic symptoms had gradually disappeared. The treatment consisted in the separation of the patient from her friends, Swedish movements gradually increased, galvanism, and the internal administration of iodide of potassium and salicylate of sodium.

**Treatment of Eczema.**—Dr. Graham Chambers read a paper on this subject. He thought the first step toward the successful management of a case of eczema was to make a thorough examination of the patient, with the object of determining the etiology and the course of the disease. Bacteria no doubt had an important part in the etiology. There was one principle in the treatment of acute eczema: that was, to give rest to the skin as completely as possible. Repeated washings with water were contraindicated. Dr. Chambers used externally a mild antiseptic sedative astringent lotion, a combination of black-wash and calamine lotion, and recommended it very highly. The internal treatment was equally important. In the majority of cases there was some systemic disturbance. Rest of mind and body were sedatives to the skin and should be secured. Confinement to bed was sometimes a great aid. Wine of antimony was a valuable remedy in subduing the inflammation of the skin.

Dr. Coventry upheld the internal treatment with mercuric chloride, gr. $\frac{1}{6}$, and calomel at times dry locally.

**The Present Status of Ergot in Obstetric Practice.**—Dr. K. McIlwraith, of Toronto, read a paper with this title. Given in small doses, t.i.d., in combination with strychnine, it delayed the onset of labor and prevented post-partum hemorrhage. In the first stage it was never given now. In the second stage it might be used to hasten lingering labor. Its advocates limited its usefulness to cases in which there was absolutely no impediment to delivery in the passages or in the size or position of the child. It must never be given to a primipara. These conditions excluded its use in most cases. Its routine administration throughout the puerperium retarded involution instead of hastening it, and it diminished milk secretion.

### GENERAL SESSION

**A Case of Coccidial Infection.**—Dr. D. W. Montgomery, of Los Angeles, Cal., reported this case. First there were general symptoms on the part of the lungs simulating tuberculosis. The process went on for some little time—a few weeks—and then the patient got a disease of the skin which consisted of large tubercles, which at first appeared as little maculæ, then grew to be small tubercles, and then large tubercles. These tubercles ulcerated and were covered with crusts, and when one was grasped and squeezed between the fingers, the inside was seen to be granular, looking like a fig. The sputum contained no tubercle bacilli. A piece of one of the crusts, examined under the microscope, was seen to contain small round bodies, having a clear double-contoured membrane and granular contents. The disease occurred in a young German, twenty-one years old, who came to California at three years of age.

**Diseases of the Kidney Amenable to Surgical Treatment.**—Dr. Christian Fenger, of Chicago, read this paper. He said that the subject was a large one. The origin of the surgery of the kidney was in 1869—thirty years ago. This new field of surgery developed rapidly, as was well seen from a review of the literature; for instance, from 1889 to 1899, what might be called the third decade, no less than eight hundred papers had been published on this one subject. Within the last five years came the surgery of the ureter. It was represented in the literature for the last ten years by about ninety papers. We could divide the surgery of the kidney into two periods. The first ten years we could term the period of nephrectomy. During this term the loss of one kidney was not considered of so much consequence as a cure of the patient. This period did not terminate after this ten years, but the dawn of the second period, or the period of conservatism, commenced. Instead of nephrectomy, a less radical operation was performed to locate the disease, without sacrificing the tissue of the kidney at its beginning. In 1881 Hahn made a nephrorrhaphy for floating kidney. But by far the most important step, and one whose consequences had been most far-reaching, covering the entire field of surgery, we owed to Henry Morris, of London, who on February 11, 1880, had the courage to open up the healthy kidney tissue and remove an oxalate of lime stone from the healthy kidney by an incision through the renal parenchyma. No operator had had the courage to do this before, except from suppurating and distended kidneys which did not bleed when cut through. From Morris' important operation dated the possibility of the development of conservatism, which was pressing forward, fighting its way toward the goal of renal surgery, which was not the cure of the patient, but the preservation for the patient of the tissue that was valuable for secretion. Morris' operation had made it possible to save the kidney from the destroying influence of stone, to operate on the healthy kidney with a stone in it. In the third decade, the latest step forward in conservatism was the surgery of the ureter. It was a somewhat limited field. With the exception of ureterectomy for tuberculous infection, which was only a small part of it, the whole of the field of the surgery of the ureter had for its aim absolutely nothing but conservation of the kidney. It was a matter of vital necessity for any one who operated on the kidneys to examine the urine for the quantity of urea before any operating was done. There was compensatory hypertrophy of a healthy kidney when its fellow had been removed or destroyed by disease. The urine must be withdrawn and collected in sterilized test-tubes. Examination of the urine must be made without delay, because urine changed rapidly by decomposition. There should be a chemical examination for albumin, blood, and sugar. There should be a quantitative examination of the urine. It was necessary to know the quantity of the urea for twenty-four hours; the life of the patient depended upon that. Dr. Fenger spoke of the use of the cystoscope and the most important step in diagnosis, the last step, the step that gave us the final answer to the question what the matter was—*i.e.*, direct examination of the kidney through an incision in the lumbar region, or the peritoneal incision. The lumbar method permitted of much more direct examination of the kidney than the abdominal one. The peritoneal was seldom resorted to, while the lumbar incision was the one in daily use. The essayist then spoke of the manner of controlling renal hemorrhage by compression either with the fingers or the clamp.

If that did not stop the hemorrhage, suturing was done. Failing this we had to pack the opening of the kidney into the pelvis and trust to the compression of the gauze. Dr. Fenger next took up the different diseases of the kidney for which operation was done, and in a classical manner described each and the indications for and against operation.

**Election of Officers.**—The following officers were elected and installed for the ensuing year: *President*, J. E. Graham, of Toronto; *First Vice-President*, A. H. Wright, of Toronto; *Second Vice-President*, M. I. Beeman, of Newburgh; *Third Vice-President*, R. J. Trimble, of Queenston; *Fourth Vice-President*, A. F. McKenzie, of Monckton; *General Secretary*, Harold C. Parsons, of Toronto; *Assistant Secretary*, E. H. Stafford, of Toronto; *Treasurer*, George H. Carveth, of Toronto.

## THE AMERICAN PROCTOLOGICAL SOCIETY.

*First Meeting, Held at Columbus, Ohio, June 6 and 7, 1899.*

**The President's Address.**—Dr. Joseph M. Mathews, of Louisville, Kentucky, devoted his address to facts showing the importance of a special study of rectal diseases. He said that there was more quackery practised in relation to the diseases of the rectum than in any other department of medical practice. These important and most serious affections were entitled to a separate and special consideration, and those who treated them should have the privilege of forming themselves into a society. Nothing would contribute more to the advancement and to the elevation of this long-neglected subject than this contemplated organization, for the principal part of our knowledge must ever come from comparing our own observations with those of others.

**Pruritus Ani.**—Dr. Tuttle then read a paper on this subject, in which he said that the term "Pruritus Ani" had for the scientific physician only a vague significance, but for its victims it was portentous of evil. The condition should be dealt with both constitutionally and locally. The speaker said that he was not a believer in pruritus ani essentialis. That there was some constitutional condition back of this symptom he admitted, and regarded it as an important element, but he insisted that there was always an exciting cause for the disturbance. Among the causes he mentioned oxyuris vermicularis, colitis, sigmoiditis, catarrhal diseases of the rectum, and uricæmia. These were the pathological conditions which he had found most often in obstinate and obscure cases. To the scientific physician all treatment must be based upon his conception of the pathology of the case. The pathological cause must be removed if possible, and the disease and not the symptom should be treated. Nitrogenous diet, alkaline diuretics, salicylic compounds, and hot baths composed the general routine of treatment. Local applications of carbolic solutions, larkspur, black wash, salicylic acid, chloral hydrate, extract of conium, camphor, cocaine, tar, etc., might all be used in one form or another.

**A Modification of Whitehead's Operation for Hemorrhoids.**—Dr. Earle, of Baltimore, read a paper with this title. After reviewing the usual methods of operations for removal of hemorrhoids, he described his own method, which consisted of clamping the tumors by sections, beginning at the fourchette, where a primary incision was made to determine the depth at which to place the clamp. After removing the tissue above the clamp piecemeal, a continuous suture, beginning at the primary incision, was inserted around the clamp. When the first section had been cut away and sutured, the clamp was removed and the suture drawn taut, when the clamp was again put in position until the whole anal circuit had been treated. The speaker had given this method a thorough trial, and unhesitatingly maintained it was safest, easiest, and by far the best method that he had ever tried. The operation was practically bloodless, and healing by first intention was secured. The convalescence was complete at the end of a week.

**Defecation.**—Dr. Thomas Charles Martin, of Cleveland, discussed "The Act of Defecation." He said that a knowledge of the anatomy of the rectum was necessary to form an appreciation of the physiology of defecation. The bundles of circular fibres which constitute the muscular element of the rectal valve have the same function as those which form the ental sphincter. It was the function of the normal rectal valve to retard the descent of the fæces, but it was obviously true that it might be the especial property of the valve in certain other than normal conditions to obstruct the descent of the fæces. The speaker's experience had convinced him that a perfect knowledge of the rectal valve constituted the key to an understanding of obstipation, rectal stricture, and their sequelæ.

**Constipation.**—Dr. A. B. Cooke, of Nashville, read a paper on "Constipation, Considered from the Standpoint of the Proctologist." He defined constipation as a diseased condition of the alimentary canal characterized by a modification of function which resulted in the pathological retention of fecal matter. He enumerated among the causes, first, those springing from the violation of hygienic law; second, defective innervation, expressed either in atonicity of the muscular coats of the intestine or in decreased secretion; third, sluggishness of the bowel function; fourth, the habitual use of purgative medicines; fifth, mechanical obstruction; sixth, painful affections of the anus. The relations between constipation and diseases of the rectum were intimate and noteworthy in that either might be cause or effect, or both, with reference to the other. Rectal reflexes were discussed at some length, and in conclusion the speaker stated as his conviction that in a large proportion of cases constipation either originated in or was maintained by causes located in the distal ten inches of the intestinal tract. If this was true, the notorious inadequacy of ordinary treatment was at once accounted for, and the duty of the proctologist in the premises became obvious.

**Rectal Adenomata.**—Dr. William M. Beach, of Pittsburg, discussed this subject. He defined an adenoma as an hypertrophy of gland tissue. He noted briefly the nature of these growths and the value of the rectal speculum in their early diagnosis and treatment. He said there were two principal types of adenomata: (1) The gelatinous, composed of elements of mucous membrane; (2) The mixed variety, consisting of mucosa and submucous cellular tissue. The adenoma with a long pedicle was benign, while growths with a broad base tended to malignity. After discussing symptoms and complications, he said that it was wellnigh impossible to locate these growths of the upper rectum by the old methods of examining the rectum: the newer and more exact methods of diagnosis and treatment of non-malignant adenomata were, however, most gratifying to both patient and surgeon. In conclusion he said that (1) rectal adenoma might be hard or soft, and contained the constituent elements of the mucosa and submucosa; (2) these growths were benign and malignant; (3) benign in their origin, they might become malignant; (4) early recognition was of first importance, which was made possible by the newer methods of inspection.

**Post-Operative Treatment of Hemorrhoids.**—Dr. J. R. Pennington, of Chicago, read a paper with this title. He said that the success of a rectal operation

depended quite as much upon the after-treatment as upon the operation itself. He used a tampon made by taking a piece of five-eighths-inch rubber tubing, about four and one-half inches long, and wrapping it with sterilized gauze until it was as large as desired, and then enclosed this tent in a special rubber cover. The tampon should be introduced through a bivalve speculum. Among the advantages claimed for the rubber-covered tampon over the gauze dressings were: (1) It was neater; (2) its removal was painless, as the granulations could not and did not penetrate or adhere to the rubber coverings as they did to the gauze or wool dressings; (3) the tender granulation sprouts were not broken off during its removal; hence there was little or no hemorrhage, which left the wound better fortified against septic infection and the healing process was greatly enhanced; (4) there was practically no pain during defecation, a point which seemed to those who had seen patients suffer almost to syncope during the first movement of the bowels, after the removal of gauze dressings, of very great importance.

The following papers were read by title: "Surgical Treatment of Non-Malignant Stricture of the Rectum," by Joseph B. Bacon, of Chicago; "The Proctoscope as a Factor in the Diagnosis and Treatment of Simple Ulceration of the Rectum," by Leon Straus, of St. Louis; "A Consideration of the Various Forms of Ulceration of the Rectum, by Lewis H. Adler, Jr., of Philadelphia; and "Rectal Carcinoma—Excision and Subsequent Colotomy," by B. Merrill Ricketts, of Cincinnati.

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

DEATH OF LAWSON TAIT—THE LATE DRS. MOIR AND CROOKE—GENERAL MEDICAL COUNCIL—ROYAL ORTHOPÆDIC HOSPITAL MANAGEMENT—HOSPITAL SUNDAY FUND—A "CONSCIENTIOUS OBJECTION"—ST. MARY'S HOSPITAL BAZAAR.

London, June 16, 1899.

Lawson Tait is dead. His health had declined of late, but the end was not anticipated by those near him, and his vigorous work and language had not prepared others for the news. On Monday while he was at his seaside residence dangerous symptoms set in, and on Tuesday afternoon he died, at the age of fifty-four years.

The last time I saw him was in public, when his burly figure, massive face, and fluent utterance in almost commanding voice gave no indication of weakness. His personality was decidedly distinctive and gave force to his arguments.

Lawson Tait was born in 1845, in Edinburgh, where his education was completed at the university. His first diploma was the license of the Edinburgh College of Surgeons in 1866. He was made fellow in 1870. The same year he settled in Birmingham, and the next took the fellowship of the English College. Two years later he was awarded the Hastings gold medal (1873) of the British Medical Association, and from that time his career has continued to be as successful as it has been prominent in the surgical and gynæcological world. His name and his writings are as well known to you as to us, and he received two or three honorary degrees from American universities as well as other distinctions. This is not the place to attempt an appreciation of his life work or a criticism of his contributions to surgery and gynæcology. It may, however, interest you to hear that he was at one time on the staff of a Birmingham daily paper, and always took an active part in the municipal affairs of his adopted home. He was on the town council from 1876 to 1885. The next year he was a Gladstonian candidate for Parliament, but the wave of unionism was too strong for him and he was badly beaten. Under more favorable circumstances he might have succeeded, for he was a powerful speaker, with plenty of the controversial spirit, a ready wit, a caustic sarcasm, and an earnest manner which impressed his hearers with the idea that he was strongly convinced that his views were right. But perhaps he shone still more as an after-dinner speaker, when wit and geniality replaced sarcasm and argument.

He desired to be buried in Gogarth cave, which is in his garden, but was once within the grounds of an abbey, and further that the funeral should be strictly private. It seems but yesterday he was with us, and last week's *British Medical Journal* contained one of his caustic letters anent the proposal for the Birmingham consulting scheme on which I recently commented, and respecting which he was in opposition to most of the local practitioners.

Robert Moir, M.D., died at St. Andrews on the 7th inst., in his sixty-ninth year. He was the second son of "Delta," and last year took part in centenary celebrations of his eminent father. He practised at St. Andrews for some twenty-five years, and had previously been in the Indian medical service, retiring as surgeon-major.

Dr. G. F. Crooke, who died suddenly on the 30th ult., was formerly pathologist to the Queen's Hospital, Birmingham, and professor at the college. Failure of health compelled him to give up this work. After partial restoration he was able to practise as a physician for a year or two, but another break-down occurred. After prolonged rest he recovered so far as to enter general practice. A few months ago he took influenza. On the day of his death he hurried to catch a train, and soon after taking his seat fainted and in a few minutes was dead. He leaves a widow and one child scantily provided for, and there is talk of raising a fund on their behalf. Birmingham will then show that she can appreciate the services of a brilliant teacher, who was heavily handicapped by ill health.

The Medical Council sat over until Friday afternoon and got through further business, much of it very uninteresting. The Hunter case was discussed, and it came out that the council as a whole did not know all the circumstances, and therefore members excused themselves from the responsibility, but this only shifts the blame on to the penal committee. This committee has been strengthened by the addition of three members, and as Mr. Horsley is one of them we may hope for more satisfactory methods of procedure. The need for amendments of the medical acts was talked about, but no definite action arrived at. The farce of marking as "confidential" minutes which are on sale at the printer's, was exposed and probably will not be repeated.

The Royal Orthopædic Hospital has again been in trouble. Some months ago it was pronounced to be unsuited for its purpose and a removal was proposed. Differences of opinion became a mere dispute. A section of the supporters then managed to replace a number of the committee and thereby obtain a majority of one. There was much talk about faggot votes, and it was proposed that members of the honorary staff should not be eligible for election on the committee. Last week there was a meeting to discuss the management, when after much wrangling the old committee carried alterations in the laws to make it impossible for the management to be taken unawares, and further to exclude the staff from the committee. Having succeeded in this they at once resigned, and so left

the control of the hospital in the hands of their opponents. These resignations were but the natural conclusion to the ebullitions of temper which these gentlemen displayed at the meeting, when the deputy chairman advised the governor "to clear out the whole of the medical staff," and stigmatized one as "the arch-conspirator" in the "raid" that had been made on the committee. The offence thus met was the representation by the staff that the sanitary state of the building was defective, and that this is so remains incontrovertible, as the medical officer of health of the district had previously ordered the drainage to be reconstructed. This is not the first time the Royal Orthopædic has come into collision with its staff. In fact, its early history is tainted with equally unreasonable proceedings. The lay members of the committee seem to have imagined the medical staff could know nothing of hospital management; and yet they themselves have given no hostages to the public as to their own abilities to deal with such a subject.

Up to last night £22,000 had been received as collected on Hospital Sunday. There is more to come, the returns not being yet made up.

A "conscientious objector" pleaded that if the baby was vaccinated he would keep them awake at night. The magistrate would not recognize the objection.

A successful bazaar on behalf of St. Mary's Hospital was held at the Great Central Hotel. I hear that some £6,000 was obtained, but ten times as much is wanted for the contemplated extension.

## A STATE SANATORIUM FOR CONSUMPTIVES.

To the Editor of the Medical Record.

Sir: In a recent number of the Medical Record you mention the bill to establish a New York State sanatorium for consumptives, among those of interest to the medical profession which failed to pass the last legislature. It may not be known to those of your readers who favor this bill, and it may encourage them to learn, that the bill in question, so far as the principles involved were concerned, met with the hearty approval of senators and of members of the assembly, and failed to pass the finance committee merely because of the expense and a desire to economize. Whether such economy is wise in the long run is a question about which opinions naturally differ, according the point of view; but the matter will come up again in the next legislature, and it is encouraging to the friends of the bill to remember that the argument of expense was also used against the bill for the State care of the insane, and that in spite of this objection a victory was won after a three-years' fight. The bill for the State care of consumptives promises to fare even better.

Alfred Meyer, M.D.

801 Madison Avenue

## TREATMENT OF PNEUMONIA.

To the Editor of the Medical Record.

Sir: The Medical Record for January 1, 1897, contains an article by Dr. Andrew H. Smith on croupous pneumonia. He therein suggests the employment of chloroform by inhalation, as he says, "to render the exudate inimical to the development of streptococci." Dr. Roberts Bartholow, in vol. c., p. 452, of the *American Journal of the Medical Sciences*, describes cases treated in a similar manner and for the same purpose by inhalations of ethyl iodide.

In two cases of pneumonia recently treated by me, it seems that an improvement upon Dr. Smith's plan was effected by using a mixture of equal parts of chloroform and formaldehyde. The chloroform seemed to lessen the disagreeable pungency of the formaldehyde.

The inhalations were employed during the first ten minutes of every hour. If the patient is sleeping, they can be used without awakening him; if he is restless and wakeful, the slightly narcotic effect of the chloroform often enables him to fall asleep.

Pain was greatly lessened. Respiration became slower and deeper. Recovery in each case was so prompt and so complete that it seemed fair to attribute much of the good result to the inhalations.

Possibly the formaldehyde may prevent the extension of the disease to unaffected portions of the lung.

E. J. Whitehead, M.D

Columbiana, Ohio, June 21, 1899

## THE PREVENTION OF SUMMER COMPLAINT IN CHILDREN.

To the Editor of the Medical Record.

Sir: Under the heading of "Summer Complaint in Children" appears an article in No. 24, vol. lv., of the Medical Record, which may be considered the incentive to the following:

Already in 1871 the writer expressed his conviction (Medical Record, vol. vi., page 357) that the great mortality caused by summer complaint was due to the fact of its being mostly considered and treated as a disease instead of a class of diseases, and for this very reason the drug treatment can be considered only seriatim as we proceed with the study of the many disturbances of the digestive apparatus of children, commencing with those of the stomach and finishing with those of the rectum, alone or in combination.

I will not repeat what Dr. Fischer has so well explained as to overfeeding, etc., but insist upon, as an additional etiological factor, the heat as it affects the peripheral nerves with its reflex action upon nerve ends of the intestinal canal.

In confining my paper to the prophylaxis of the evil, I, however, like Dr. Fischer, may be justified in speaking of summer complaint as a unit. The whole prophylactic treatment of summer complaint can be summed up in the word "water."

The first rule is to guard against overfeeding, the principal cause of infantile summer diarrhœa. To that purpose parents and nurse must be instructed that, whenever a baby cries on account of what is generally considered to be hunger, it should be given first of all some good (sterilized) water or some very weak fennel-seed tea, only slightly sweetened. Too often the little one cries because of thirst, and it is fed, given milk. Food not being wanted at that time the child may be justly said to be overfed and thus exposed to all the disastrous consequences of summer complaint. Give food often, but always in small quantities, and let it be preceded by some water or slightly acidulated drink, as recommended by Dr. Fischer in his article.

The scrupulous observation of this rule, never to give food when really only drink is wanted, cannot be too strongly impressed upon the minds of parents and nurses as one productive of the best results.

The second rule is "Keep the baby cool." Visits to the seashore or the mountains or ocean voyages may one or all be very good, but are within reach of only the few. And still it is necessary that the baby be kept cool, free from fretting with heat. How often do we hear mothers say: "That poor baby cried all day or night, suffering from the heat and possibly

teething besides; it was so fretful I was afraid it might go into fits." Tell her, and all, that all this is avoidable, and tell her how to apply rule No. 2.

It is within the reach of all to have a wash-tub always partly filled with sun-warmed water. However small the baby, never let it become heated; bathe it or let it bathe as often as necessary (two to ten times per day) to keep cool during hot weather. This rule systematically carried out will prove of inestimable value. It generally takes but a few days before the children will be, to use a certain mother's expression, just crazy for the tub.

It is reflex irritation which causes diarrhœa as a complication of difficult dentition; it is the nerve-sedative action of chloral enemata which proves so beneficent and life-saving in cases of Asiatic cholera. It is this same principle of cause and remedy which is recommended, and forms the basis of our successful prophylaxis in cholera infantum.

E. Steiger, M.D.

Prairie du Chien, Wis.

## AN EXAMPLE OF EASTERN SANITATION.

(From our Special Correspondent.)

"Sir," said a sojourner in the East in my hearing about a week ago, "there is not a finer town in the East than Byrout—barrin' the smells."

I admit he was a pilgrim and a sojourner—an outspoken, genial recruit from the Emerald Isle, perhaps; his modicum of brogue betrayed him anyway.

He told the truth, nevertheless.

Beyrout—or Beyrouth, as the French have it—is an indistinguishable blend of perfume, odor, and filth. And these are all so inseparably mingled, so inextricably amalgamated, that we cannot blame the authorities for their tacit acceptance of the fact.

When Satan pointed from Palestine to a famous city, the words spoken were, according to Milton:

> "Westward turn thine eye;
> On the Ægean shore a city stands
> Built nobly; pure the air and light the soil:
> Athens, the eye of Greece, mother of arts
> And eloquence."

But did Satan ever enter into Athens? Did he ever examine the streets, the purlieus thereof, not to speak of the modes and manners of the citizens of the ancient city? Maybe he would have altered his mind if he had done so—if he had a mind at all; and maybe he would not have been—leaving out details—so enthusiastic.

So far Satan for Athens.

Now let us turn to our Eastern seaport.

It does look noble—more or less—from the sea. So it seemed to us. When we first saw it, Lebanon was like unto a mighty cloud, pure and white as driven snow, cut like a cameo on a distance of steel-blue, cloudless sky. We were about fifty miles away from the town, or city, as some will have it, and it was about half an hour before sunrise.

"What a magnificent mass of vapor!" said the poet of our party, referring to the famous mountain-top.

"Looks more like a cauliflower," said our genial idiot—the droll man of our assembly.

"Why, that's just Mount Lebanon, where King Solomon got his cedars from to build the temple in Jerusalem," explained the chief engineer—evidently a Scotchman—and passed on his way to the stoke-hole.

Then—the pity of it! From the sea—a stately town, built on a promontory, with every facility that nature could give it for perfect sanitation. Built below graceful undulations of foothills—the rootlets of the great snow-clad mountain—clad with pine and olive tree.

So we saw it, and so we felt it—fifty miles away. And then we landed and found Beyrout—indeterminate odors! inextinguishable scents!

We walked some half a mile or so to our hotel, and passed by several families of camels, mules, and donkeys, who seemed to have been passing the night in making a magnificent dunghill on the Sultan's highway.

People say that the smell of the camel is good for health and tends to sleep. It may be so; but, all the same, he has no right to defy the sanitary authorities by other methods.

Our landlord was an excellent man. He had been dragoman or interpreter in a previous Soudan war, and spoke English like a book. This pleased us well, as our Arabic was not sufficiently fluent to express ourselves about the dirtiness of our adopted town.

Our grill room was situated beside the water-closet, and the kitchen was in the immediate neighborhood, with a water-closet all to itself in the corner thereof.

There was a blend of garlic and ammonia in the atmosphere when we entered. As lunch came on, this was interspersed with a flavor of roast beef and musk, which a lady introduced—a handsome lady, too.

The presiding goddess of the cuisine seemed to have in her hands the direction of the defecating and urinating department—at least, when compelled to do so we personally had to perform both functions in her immediate presence—and she did not seem to care one iota.

Strange! there was not one single case of illness during our two-month stay in this hotel.

There was an average of twenty of us at table. We seemed to have been a healthy, hearty lot; we ate well, slept well, enjoyed the blend of perfume, and defied the microbe.

But then we were living just over the sea; and perhaps the beat of the waves on the rocks and the wash of the salt sea-water had something to do with it.

So we came to Beyrout; and it is likely that we will tell you more of it anon—of the poor, the halt, the lame, the blind; of the diseases, of the lepers in our midst, and of the sicknesses that come from want of care.

Beyrout, Syria, May, 1[illegible]

## New Instruments.

### A URINAL FOR CASES OF VESICO-VAGINAL FISTULA.

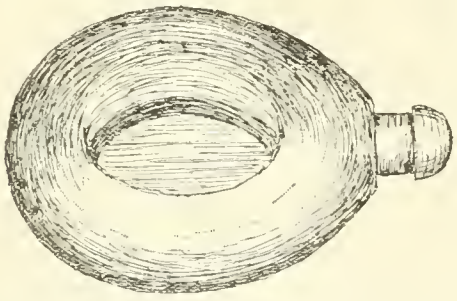
By O. W. PHELPS, M.D.,

Warren, Mass.

I have had under my care a woman over seventy years of age, who within a year and a half had undergone three capital operations for removal of carcinoma of the generative pelvic organs. At the first operation the left ovary was removed; eighteen months later the other ovary having become diseased was removed, also considerable cancerous tissue from the abdominal wall starting from the scar of the first incision. The uterus was also cancerous, but on account of the patient's condition it was not deemed prudent to remove it at this time, but about two weeks later it was removed. The operation proved very serious, and left the patient with a vesico-vaginal fistula, for which an operation is at present impracticable. Although there was good recovery from the other operations, still age, the dread of ether, and the possibility of a return of the cancer were elements against a fourth operation. But the constant dribbling of urine night and day seri-

ously disturbed sleep and kept the external parts constantly wet, and the skin irritated and tender to an extent that rendered life almost unbearable. The general health was suffering seriously from the physical discomfort and mental depression for which there seemed to be no relief.

A rubber bed-pan and soft-rubber urinal gave but little relief; in fact, the latter seemed entire impracti-

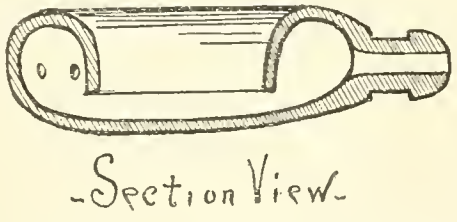


cable, nor could I find any other device in the catalogues of surgical supplies that promised any better.

Under these circumstances I conceived a plan by which to collect the urine in the vagina and conduct it out into some convenient receptacle without its coming in contact with the external parts.

This I have accomplished by a vulcanized rubber instrument, shown in the cut. It is perhaps best described as an oval snuff-box with a hole cut in the top and the edges bent down in to about one-eighth inch of the bottom, and a nipple for a rubber tubing to be attached on one end. This is worn like a pessary. It has three or four small perforations at the upper end, but most of the urine is supposed to get in over the top. The opening in the top is filled with a pledget of absorbent wool or other material to prevent the soft parts settling into the opening, and thus being irritated and at the same time obstructing the water. The urinal presses more firmly against the lower part, where it comes against the sphincter vaginæ, than upon the upper and softer portion, so the urine is not so likely to come out beside the tubing as to get within the ring and thus be conducted by the three-eighth inch tubing which connects the urinal with the receptacle. For the latter I use the bag belonging to an ordinary soft-rubber urinal; this is strapped to the leg just at the bend of the knee, and completes the instrument.

Of course the urinal requires to be removed daily and thoroughly cleansed, and the pledget of wool to be replaced by a fresh one. This the husband does,



or it may be done by a nurse or even the patient herself.

In twenty-four hours after this urinal was introduced, my patient, who was before haggard and worn, and to whom life seemed hardly worth living, was relieved of the external irritation; the mental depression gave place to a cheerful countenance and a general appearance of well-being.

She can go about the house with comfort, doing light work and entertaining company, can sleep nights and find herself dry and rested in the morning; and in fact, whereas she was repulsive to herself and in constant fear of becoming so to others, she is now enjoying reasonable comfort and enabled to minister to the happiness and pleasure of those about her.

## MODIFIED BIVALVE VAGINAL SPECULUM.

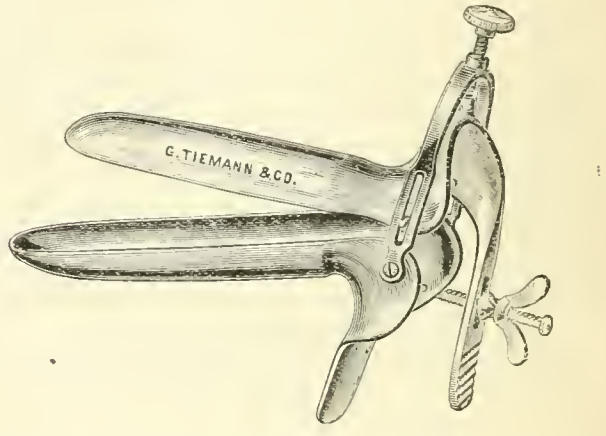
By J. J. MONTGOMERY, M.D.,

LUZERNE, N. Y.

I believe that every physician doing a general practice in the country, and out of the reach of skilled assistants, has recourse more or less to the use of the bivalve speculum in his vaginal work. I believe also that most patterns of this instrument that have as yet been devised are faulty in many respects.

In the accompanying cut is shown a speculum in which the aim in its construction has been to retain all the good qualities of the older instruments, to eliminate their defects, and add new and improved features. I have used it in my daily work for nearly two years, and find that it comes nearer meeting the requirements of a bivalve vaginal speculum than any other I have seen. It is aseptic. It is self-retaining.

The orifice is dilatable and is regulated by a thumb-screw on top, instead of below as in most other specula. It can be used with the patient lying in any position, especially the dorsal, and there is no long shank to reach downward over the perineum and rest upon the bed, couch, or table on which the patient is lying. The mechanism is so balanced that the upper



thumb-screw controls the upper blade, while the lower thumb-screw and lever control the lower blade. The instrument was made for me in two sizes by Messrs. George Tiemann & Co., of New York City.

---

**Inequality in the Inheritance of Health.**—There is, it is true, as great an inequality in the inheritance of health as in the heirship of wealth or brains. Some are born with a fortune of vigor and soundness so large that not a lifetime of eager squandering will leave them poor, and others enter the world paupers of need so dire that no charity from medicine can ever raise them to comfort; but most of us have just that mediocre legacy of vitality which renders us undistinguishable units in the mass. It lies in the hands of each to improve or waste that property as he chooses, for there are self-made men physically as well as financially; those who because of ancestral wastefulness have only a sixpence of health and turn it into a fortune; and there are spendthrifts of health who come to as sorrowful cases as spendthrifts of gold. The body is a realm where a wise and frugal ruler brings happiness as surely as a foolish one insures distress, and wisdom here as elsewhere lies in learning and obeying natural laws.—Elizabeth Bisland, *North American Review* for April.

**Vaginal Hysterectomy.**—I believe that a judicious combination of clamp and ligature will ultimately become the usual method adopted.—A. Martin.

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 1, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 140 | 139 |
| Typhoid fever | 30 | 8 |
| Scarlet fever | 93 | [illegible] |
| Measles | 278 | [illegible] |
| Diphtheria | 191 | 31 |
| Laryngeal diphtheria (croup) | 11 | 7 |
| Cerebro-spinal meningitis | 0 | 5 |
| Chicken-pox | 19 | [illegible] |
| Smallpox | 7 | [illegible] |

**A Medical Rear-Admiral.**—Through the action of the naval personnel bill passed by the last congress, Dr. Van Reypen, the surgeon-general of the navy, in common with the other bureau chiefs receives the rank and pay of a rear-admiral.—*Sanitarian.*

**Damages for Typhoid Fever.**—A man in Philadelphia has been awarded $1,500 damages for an attack of typhoid attributed to contamination of his water supply by the overflow from a sewer left uncompleted by the city.—*Sanitarian.*

**"Osteopaths, Take Notice."**—Under this heading *The Medical Fortnightly*, May 15th, writes: "One of the amusing features of the tornado which caused such sad havoc at Kirksville, Mo. (the home of the osteopaths), is to be noted in the following item, which appeared in the Associated Press dispatches the following day: "All business is suspended, and only stores open for business are those dealing in drugs."

**Oxygen in Pneumonia.**—Of the value of oxygen in the relief of dyspnœa and cyanosis it is difficult to give a final judgment. The opinion is slowly but surely gaining ground among the great clinicians that oxygen has been much overrated in the treatment of pneumonia.—Morris Manges.

**French Naval Death Rate.**—Professor Vincent, in his report to the French Academy of Medicine, stated that, according to his statistics, drawn up from 1888 to 1897, about half the deaths—viz., 46.8 per cent.—in the French navy resulted from tuberculosis. The chief victims are, Professor Vincent states, those who are compelled to live in the interior of the ship—the machinists and stokers and lower-grade officers. On that account he urges stringent prophylactic regulations for the naval as well as the land forces. Another authority, Rey de Méricourt, calls attention from a hygienic point of view to the overcrowding on board ship.

**Coffee.**—In 1896–97 the amount of coffee, raw and manufactured, upon which duty was paid in our custom houses was only about 12,000 tons, whereas according to *Le Bulletin de Statistique et de Législation Comparée*—a French official publication—the total amount consumed in Europe and the United States was no less than 623,320 tons. Holland, we learn from the same authority, is the country where the drinking of coffee is most in vogue, the quantity disposed of per head per annum being upward of ten kilogrammes. Denmark and Belgium come next with seven and five kilogrammes respectively, while in France the allowance per inhabitant is no more than one and a half kilogrammes. On the Continent it is apparently the sum levied as duty which determines the amount consumed. In Holland coffee is entirely untaxed. In Denmark and Belgium the charge is insignificant, but in France it amounts to the almost prohibitive rate of 156 francs per one hundred kilogrammes, or about 7d. a pound avoirdupois. The tax with us is only 1½d. a pound for the raw article and 2d. when it is manufactured, so our trifling consumption of about a third of a kilogramme per head cannot well be due to fiscal causes. The production of coffee is said to be increasing rapidly in South America and to be assuming large proportions in Central Africa. In the Rio districts alone the augmented output for the four years ending 1897 was equal to 4,000,000 sacks, or about 240,000 tons. Writing in the *Revue des Deux Mondes* for July, 1898, M. de Castries says: "They are planting at least 600,000 coffee plants every year in the Congo Free State, and everything favors the hope that in a few years the output will have risen to upward of 26,000,000 kilogrammes." If this is the case the price of coffee should soon fall, when in all probability our consumption of six pounds of tea per head per annum will suffer a diminution. There can be no doubt that coffee affects the human economy in a peculiarly agreeable and beneficent manner. It is fairly cheap, easily prepared, although less so than tea, an admirable calorifacient, and there is nothing whatever to forbid its habitual use in moderation whether with meals or at other times. On the whole, it would seem that its more extended utilization is highly to be desired.—*The Lancet.*

**Ovaries: Results of Complete Extirpation.**—(1) The woman becomes absolutely sterile. (2) Menstruation ceases in about ninety-five per cent. of the cases. (3) The uterus and to a less extent the vagina and vulva undergo a process of atrophy. (4) The nervous symptoms of the menopause appear abruptly and violently—viz., heats and flushes, perspirations, palpitations, giddiness, depression of spirits, and a generally unstable condition of the nervous system. (5) In a considerable majority of cases there is a diminution or total abolition of the sexual instincts. (6) The patient has a tendency to obesity.—Christopher Martin.

**The Decreased Birth Rate in France.**—One hundred years ago it was reckoned that the Great Powers of Europe numbered about 98,000,000 inhabitants, and of these 26,000,000, or 26.5 per cent., were French; to-day, out of about 300,000,000, only 38,000,000, or about 12.6 per cent., belong to France. As Dr. Henry May has shown, the English birth rate is also declining, though at a much less rate, and it is probable that the same causes as are at work in France are making their influences felt in England also. The principal of these causes is undoubtedly one which is well described by a recent writer on the subject in the *Journal de Médecine de Paris*: "The dearth of children in France is due to the fact that the French people do not choose to have families. This defective natality cannot be laid to the charge of poverty. The richer a Frenchman, the fewer children he has. This is equally true in town and country. . . . Grenoble, one of the poorest parts of Paris, heads the list for births, while the Champs Elysées is at the foot." That the above view is correct is borne out by a consideration of the fecundity of marriages. The number of legitimate births annually per 1,000 married women is 115 in France, 184 in Italy, 186 in Norway, 190 in England, 202 in Germany, and 205 in Scotland. According to the 1891 census, there were in France 22 families out of every 100 which had only 2 children living, and 24 out of every 100 families which had only 1 living child. The so-called neo-Malthusianism is principally responsible for the above disastrous conditions. Malthus and his disciples, in their zeal to pre-

vent an over-population—which is, to say the least, a very remote danger—have "o'erleapt" themselves, and the French will have them to thank if ever she suffers eclipse as a military nation.—*Medical Magazine.*

**The Signs and Tests of Death.**—(1) Cessation of respiration—(*a*) Mirror test; (*b*) feather test; (*c*) water or mercury test; (*d*) stethoscopic test; (*e*) rhythmic traction of the tongue. (2) Cessation of circulation—(*a*) Stethoscopic test; (*b*) ligature test; (*c*) scarification and cupping; (*d*) opening of an artery; (*e*) needle test (Cloquet's); (*f*) fluorescine test; (*g*) injection of ammonia (Monte Verde's test); (*h*) diaphanous test (Carriere's); (*i*) Roentgen ray. (3) Changes in the eye—(*a*) Test by bright light; (*b*) test by mydriatics; (*c*) test by ophthalmoscope; (*d*) test by ophthalmatonometer. (4) Loss of animal heat—Temperature test. (5) Loss of sensation and of motion—(*a*) Electric test; (*b*) heat test; (*c*) caustic test. (6) Muscular flaccidity and contractility. (7) Cadaveric ecchymoses, lividity, or hypostases. (8) Cadaveric rigidity, cadaveric spasm, rigor mortis. (9) Putrefaction.—J. HEROLD.

**Meat and Cancer.**—Verneuil, some years ago, said that he and other hospital surgeons in Paris had been struck by the much greater number of cases of cancer of the tongue and other visible parts that came before them than had been the case thirty or forty years before. He attributed the fact to the increasingly carnivorous habits of the population. The vegetarians naturally hailed this suggestion with enthusiasm, till it was pointed out that cancer is just as prevalent among the mild Hindus, to whom the flesh-pot is an abomination, as among the "cow-eaters" whom they despise. Among ourselves there seems to be a widespread popular belief that the pleasant and harmless if not exactly necessary tomato has something to do with the production of cancer. Whenever the question of cancer is touched upon in the lay press, this tomato theory is sure to be brought forward with a gravity worthy of a better cause.—*Practitioner.*

**Mosquitoes and Malaria.**—The Italian observers, Grassi, Bastianelli, and Bignami, who are associated in carrying out a series of investigations at the hospital of Santo Spirito, with the object of throwing light upon the etiology of malarial fever, have again met with success in their inoculation experiments with mosquitoes. On this occasion only one species of these insects was employed in the experiment, namely, Anopheles claviger, captured as before in the adult stage in the malarious region about Maccarese. The subject of the experiment was a young man who had never suffered from malarial fever, and who was received into the hospital of Santo Spirito for hysteria about four years ago, during which time he has been constantly under observation and has had no kind of fever whatever. This man for nineteen days slept in a room in which were set at liberty from time to time numerous specimens of Anopheles claviger. On December 2d (eighteenth day) he began to feel unwell, and on December 3d the blood on examination was found to contain the parasites of malarial fever, exclusively of the common tertiary type (the spring tertian of Italian writers). This form of fever is prevalent at Maccarese. Considerable difficulty is experienced in continuing these experiments on account of many of the mosquitoes dying and others refusing to feed. This is probably due to the lateness of the season.—*Scientific American Supplement.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, plague, and leprosy have been reported to the surgeon-general of the United States Marine-Hospital service during the week ending July 1, 1899:

### SOME POINTS IN THE SYMPTOMATOLOGY, PATHOLOGY, AND TREATMENT OF DISEASES OF THE SINUSES ADJACENT AND SECONDARY TO THE ORBIT.[1]

By CHARLES STEDMAN BULL, A.M., M.D.,

NEW YORK.

The subject of this paper may be said briefly to be the "Orbital Symptoms and the Treatment of Sinus Disease." The location and extent of sinus disease adjacent to the orbit, and involving it secondarily, frequently decide not only the question of operative interference, and the nature and extent of the operation itself, but also the point whether any operation is justifiable.

The frontal sinus, the ethmoid cells, the sphenoidal sinus, and the maxillary antrum are often the seat of disease which subsequently extends to the orbit. It is a well-known fact that tumors of the bones of the skull, or of the sinuses contained within these bones, may extend in every direction from one sinus or labyrinth to another, and often exist for a long time and reach a large size before appearing in the orbit. The growth of these tumors is usually slow and insidious, though occasionally very rapid. Extensive disintegration of the ethmoid, sphenoid, and superior maxillary bones, from tumors starting in their respective sinuses, may have already occurred before the presence of such a growth is manifested in the orbit by the usual signs of displacement or protrusion of the eyeball, pain on pressure along the orbital walls or directly backward, and the visible or tangible presence of the growth itself within the orbit.

**The Frontal Sinus.**—With the exception of the true osteoma, the frontal sinus is rarely the seat of tumors primarily. The most frequent diseases met with here are of an inflammatory character, viz., mucocele and empyema, the latter being the more common of the two. Both of these diseases may be acute or chronic, the latter type forming the great majority of the cases. The symptoms are practically the same in both, as a chronic mucocele usually becomes an empyema.

Abscess of the frontal sinus is usually an affection of adult life, and does not occur in childhood, as the sinuses are not developed at this period of life. It is met with oftener among men than among women, probably because the sinuses are more developed in men than in women, the infundibulum is wider, and communicates more directly with the external air through the nasal fossæ, and hence are more exposed to the entrance of infectious agents. The left frontal sinus is more frequently attacked than the right, but the reason for this is unknown. The suppurative process may begin in one sinus, perforate the bony septum between the two sinuses, and involve the other sinus secondarily.

[1] An address delivered before the combined sections of ophthalmology and of otology and laryngology of the American Medical Association, June 7, 1899.

Symptoms: In chronic empyema there may or may not be supra-orbital pain, which is sometimes intense. There are, however, many cases in which there is never any pain during the development of the abscess. In the acute form of the disease there is always severe pain over the eyebrow. If the process is confined to the frontal sinus, there is usually no other symptom until late in the disease. If there is sensitiveness on pressure over the frontal boss, swelling along the lower surface of the supra-orbital margin and inner wall of the orbit, and displacement of the eyeball downward and outward, it is probable that the disease has extended to the ethmoid cells. If there are coryza, ozæna, and a purulent discharge from the nostril, the nasal meatus has become involved, and the diagnosis is certain. Distention of the frontal sinus can generally be easily recognized by the site of the swelling. It is higher up and farther back than the site of the lacrymal sac, and it has hard, resisting walls. Occasionally a spontaneous opening occurs by absorption of the bony walls, and the symptoms are then those of a cyst. The orbital symptoms usually advance slowly, though occasionally we meet with a very rapid progress. But there are cases in which a sort of intermittence in these symptoms appears. If the swelling of the mucous lining closes the fronto-nasal canal temporarily, a violent supra-orbital pain will be suddenly produced by the accumulation of fluid within the sinus. Sometimes violent neuralgic attacks occur, usually at the same hour in the morning. These attacks are characterized by continuous pain with severe exacerbations, radiating around the orbit and within the zone of distribution of the ophthalmic branch of the trifacial. They are accompanied by injection of the conjunctiva, lacrymation, and photophobia. After several hours the attack subsides. These patients have usually had "grippe" with rhinitis and profuse secretion. At other times I have seen the attack accompanied at its height by paresis of accommodation.

Empyema of the frontal sinus is very frequently preceded or followed by suppuration of the maxillary antrum. The pus from above may flow into the middle nasal meatus, into which opens the "ostium maxillare," and there set up a similar suppurative inflammation, and the flow of pus from the antrum with the attendant symptoms may often be the first signs of disease of the frontal sinus. In rare cases, however, it would seem as if the disease began in the antrum and extended upward to the frontal sinus. These cases are generally due to an attack of "grippe."

Etiology: The etiology of suppuration of the frontal sinus is somewhat obscure. The predisposing causes are syphilis, tuberculosis, erysipelas, typhoid fever, scarlatina, influenza, inflammatory lesions and polypi of the mucous membrane of the nasal fossæ, and wounds of the superior orbital margin. Both syphilis and tuberculosis may produce an osteo-periostitis of the frontal bone, followed by extensive caries and necrosis and profuse suppuration, and the frontal sinus may be invaded by the pus from without. In erysipelas, the disease process extends through the mucous membrane of the nasal fossæ to the infundibulum, and thence to the frontal sinus. But in order that suppu-

ration should occur in a frontal sinus, there must be an entrance and proliferation of pyogenic microbes in the sinus. The latter may penetrate directly into the sinus through the nasal fossæ, with or without infection of these fossæ, either by way of the infundibulum or by the lymphatics. The mucous membrane of the sinus swells and becomes thicker, and thus the calibre of the infundibulum is narrowed and eventually obliterated, and then the pus collects in the sinus and gives rise to the usual symptoms. When a mucocele becomes an abscess, there must have been present a second element of an infectious nature.

Some assistance in diagnosis is occasionally gained by exploration of the sinus by transillumination with an incandescent lamp, the lamp being applied just beneath the orbital arch. The diagnostic value of this method is, however, *nil*, unless it prove positively the presence of pus in the sinus. If the latter exist, the area corresponding to the extent of the sinus, which should appear illuminated, is in shadow, owing to the presence of pus. Transillumination is of much less value as a means of exploration of the frontal sinus than it is for the maxillary antrum. This method of examination as an aid to diagnosis is very uncertain. It is well known that the sinuses vary in size and shape in the same individual. One sinus may be completely wanting, or entirely filled by a bony tumor. The dimensions of the frontal sinus are very variable, and they sometimes communicate with each other, or with the ethmoid, or with the orbit. All these facts contribute to the uncertainty of the results obtained by transillumination and to the possibility of a faulty diagnosis.

Treatment: An abscess of the frontal sinus having been recognized, the indications are to open it as soon as possible, drain it carefully, inject bactericidal solutions, and put a stop to the suppurative process. In some rare cases of acute empyema, it may be possible to open the sinus internally by enlarging the infundibulum through the nose with a curette, and thoroughly irrigating the sinus by means of a catheter. But this is an extremely difficult procedure, as every one knows who has tried it, and never entirely satisfactory. Moreover, the opening of the ethmoid cells, which is often necessary in these cases, through the nasal meatus, is a difficult and dangerous undertaking. Hence it seems fair to state that the attempt to cure an empyema of the frontal sinus by enlarging the infundibulum in the nose, and by irrigation of the sinus from the nasal fossa through the fronto-nasal canal, is justifiable only in very recent cases and where the natural conformation of the nose admits of such interference.

In all chronic cases, and in most of the acute cases, the frontal sinus should be opened externally by the Ogston-Luc method. The region of election is at the lowest part of the anterior wall of the sinus, immediately above the root of the nose. The external incision should be from an inch and a half to two inches in length, and should extend far enough toward the opposite side to facilitate an opening into the other sinus, if such a procedure prove to be necessary. The operation is entirely devoid of danger, and if properly done always succeeds in effecting a cure. Luc prefers to open the sinus by means of the gouge and mallet, and advises that after the removal of the first splinter or scale of bone, the deep or posterior wall of the sinus be protected by a metal shield against any possible danger of injury from the further use of the gouge. I have found it equally easy to use at first a small trephine, half an inch in diameter, and then to enlarge this opening by the gouge. The dimensions of the opening into the sinus depend somewhat upon the extent and chronicity of the lesion, but should always be large enough to admit of free exploration of the entire sinus. After evacuation of the pus, all fungosities and osteophytes should be thoroughly removed by the curette. To this end it is better to take away the entire anterior wall of the sinus. The septum between the sinuses should then be examined, and if found perforated, it should be removed by the gouge, and the cavity of the opposite sinus thoroughly curetted. To do this, it may be necessary to open through the anterior wall of this sinus, which can be done in the same way by extending the external incision beyond the median line.

In view of the somewhat frequent occurrence of abscess of both sinuses, some operators have advised opening the frontal bone in the median line, and extending the opening toward each sinus, and I have done this recently with very satisfactory results in one case.

In most of the chronic cases it will be found necessary to open freely into the ethmoid cells, and in every case a large, free opening must be made through the fronto-ethmoidal canal into the nasal fossa of the corresponding side. The whole cavity is then to be washed out with a solution of mercuric bichloride (1 : 1,000), the irrigation being kept up until the fluid runs freely from the nose. A rubber drainage tube is then introduced and carried from the nasal cavity well up to the bottom of the frontal sinus, and the irrigation again repeated. The external wound is then to be completely closed by sutures going through the entire thickness of the skin, and the usual antiseptic dressings are to be applied. The immediate closure of the external wound shortens the period of healing and reduces the ultimate cicatricial deformity to a minimum.

In some cases it will be found that nature has caused a fistulous opening, which is usually found just beneath the superior orbital arch, at the supero-internal angle of the orbit. Luc states that the presence of this fistulous tract should not contraindicate the performance of the above operation. After the latter has been done and the sinus completely cleaned out, the fistulous tract may be treated in the usual way by incising the tract throughout its entire length, and then freshening the edges and stitching them together. This seems sound advice, though I have had no experience with fistulous openings into the frontal sinus.

All attempts to relieve or cure chronic empyema of the frontal sinus by intra-nasal treatment alone should be regarded as futile. In view of the frequency with which both frontal sinuses are involved in the process, Moure suggests making a horizontal incision in the usual place, but extending across the glabella to the opposite side, and then making a vertical incision upward in the median line, thus admitting of the dissection of two flaps of skin, and exposing the anterior wall of both frontal sinuses, which may then be opened in the usual way.

**Tumors of the Frontal Sinus.**—The only tumor originating in the frontal sinus which is encountered with any degree of frequency is the osteoma or ivory exostosis. By its pressure it causes absorption of extensive portions of the bony wall, and eventually an opening not only into the cavity of the orbit, but also into the anterior fossa of the skull. Its etiology is extremely obscure. It has been attributed to syphilis, gout, rheumatism, and traumatism, but it is well to look for the predisposing cause at least in an abnormal embryonic condition of the bone cells.

Symptoms: Osteomata always grow very slowly and painlessly. They are never sensitive on pressure, and when they cause pain it is either from pressure on some nerve or from some localized inflammation. As the tumor grows, the eyeball is displaced, and there may even be such extreme exophthalmos that the eyelids cannot be closed over the eye, and the cornea ulcerates. There may be marked disturbance of vi-

sion, and the usual ophthalmoscopic evidences of neuro-retinitis and atrophy of the optic nerve. The diagnosis is made from the location of the tumor, its extreme hardness, its immobility, and its direct connection with the bone. It may be confounded with distention of the frontal sinus or of the ethmoid cells. The prognosis is favorable if the tumor has not encroached upon the anterior fossa of the skull.

Treatment: This consists solely in its operative removal. Owing to the extreme hardness of the tumor, its removal is very tedious and a matter of considerable difficulty. If the tumor is of great size and has probably involved the anterior cerebral fossa, it may be wiser not to attempt its removal, owing to the danger to life. The periosteum must first be incised and carefully stripped from the tumor for some little distance beyond its base in all directions. Then a narrow groove should be cut with a chisel or gouge and mallet around the base, the blows with the mallet being made gently and somewhat rapidly until the tumor is loosened. Then a gentle rocking to and fro will usually suffice to detach it. If the tumor be found of ivory hardness, small holes may be drilled in it by means of a dental engine, and the operation subsequently completed with the chisel and mallet. The usual antiseptic dressings are then applied, and suppuration rarely occurs.

**The Maxillary Antrum.**—Diseases of the antrum are by no means so rare as has been supposed, and this is probably due to the fact that the antrum has not always been carefully examined. The inflammatory diseases most frequently met with here are mucocele and empyema, the latter being by far the more common. The subjective symptoms are practically the same in both.

**Empyema of the Antrum.**—Pus may collect in the antrum as a consequence of inflammation extending from the nose, or of empyema in the sphenoidal antrum, ethmoid cells, or frontal sinus, or it may originate in the antrum itself. If the collection of pus be considerable, it may flow into the nasal meatus through the ostium maxillare, and out through the nostril or back into the pharynx. The most common source of purulent inflammation in the antrum is disease of the teeth or caries of the alveolar arch, especially of the posterior molars, forming first subperiosteal abscess, and then abscess of the antrum.

Symptoms: Pain is the most constant symptom, though, if drainage be free, it may be slight or entirely absent. It is located in the cheek, is frequently periodic in character, and is often accompanied by an unpleasant odor from the decomposition of retained secretions. The escape of pus from the antrum is positive evidence of disease. The orbital symptoms are more or less displacement or protrusion of the eye, orbital cellulitis and chemosis, loss of vision from neuro-retinitis or atrophy, due to pressure on the optic nerve and obstruction to the return circulation, and panophthalmitis from strangulation of the tissues. Many cases of empyema are so slow and insidious in their progress and so slight in their symptoms, that their existence is ignored by the patient, until some violent retro-ocular or orbital inflammation or some grave cerebral complication demands a careful investigation of the cause. There are other cases in which, in the course of a maxillary empyema of dental origin, are manifested symptoms not due to any visible involvement of the cellular tissue of the orbit, such as narrowing of the visual field, atrophy of the optic disc, and irido-choroiditis with opacities of the vitreous. This makes it necessary to consider how intimately connected are the maxillary antrum, the sphenoid antrum, and the ethmoid cells with each other, and how comparatively near each other in the nose are the openings of these sinuses. Masked by the readily recognizable symptoms of empyema of the maxillary antrum, a similar condition in the sphenoid and ethmoid may be overlooked. Lesions in these sinuses may explain a certain number of orbital complications which have hitherto been attributed to reflex action. It is necessary to exclude disease of the sphenoid or ethmoid sinuses before we can make a positive diagnosis of empyema of the maxillary antrum alone. Owing to the ostium maxillare being the lowest of the three openings, the antrum may frequently become the receptacle for pus coming from the other sinuses, and guided into it by a semilunar fold of mucous membrane in the nose.

The extension of the disease from the antrum to the orbit may take place theoretically in three ways, viz.: (1) By direct propagation through the bony roof of the antrum. (2) By means of the lymphatics. (3) By means of the veins. The first and by far the most frequent channel through the floor of the orbit occurs by osteo-periostitis. The second would affect the eye and orbit by means of a retro-ocular inflammation. The third would cause an orbital cellulitis without any periostitis. In the great majority of the cases the orbital cellulitis is the result of an osteo-periostitis of the orbital floor, which is very thin and often shows openings, through which the infection is propagated directly from the antrum to the orbit. If the case pursues an acute course, we have a train of symptoms which is easily followed, beginning with dental caries, inflammation of the sinus, closure of the ostium maxillare, symptoms of pus retention, necrotic osteitis of the roof of the antrum, orbital cellulitis, and then, if the case is not radically treated, osteitis of the roof of the orbit, abscess of the brain, and death. If the inflammation is a chronic one, its course is much slower and more insidious, until a marked failure of vision reveals an optic neuritis or atrophy due to retro-bulbar neuritis.

We are sometimes aided in our diagnosis of antrum disease by employing the method of transillumination. This method has very marked limitations, but is more useful and gives more real diagnostic aid in disease of the maxillary antrum than in affections of any of the other sinuses adjacent to the orbit. Certain possibilities should not, however, be forgotten. The typical triangular pyramidal form of the antrum is exceptional. The floor of the sinus may be on a lower plane than the nasal fossa, by excessive absorption of the alveolar border. The antrum of the other side may be higher, and the illumination might lead us to diagnosticate an abscess in the antrum which stood higher. One sinus may be entirely absent or filled by a solid exostosis.

The examination of the antrum by illumination must be made in a dark room. The method devised by Heryng, improved by Vohsen, and still further improved by Luc and Escat, is probably the best. A four—or five—candle-power lamp, connected with a battery and a rheostat by means of ordinary insulated wires covered with rubber tubing is placed in the mouth, the lips are closed over the connecting rubber tubes, and connection is made. If the antrum is normal, the face takes on a ruddy glow, the brightness differing in spots according to the thickness of the solid parts of the face. The brightest spot will be at the lower margin of the orbit, where the wall is thinnest. If the light encounters pus, or polypi, or solid tumors, there will be more or less darkening of the corresponding side of the face. Burger attaches much importance to the illumination of the eye by the transillumination, the signs of which are a red glow from the pupil. The Heryng method of illumination is valuable only when the corresponding nasal fossa is perfectly healthy, and contains nothing to intercept the luminous rays. The method of Escat, the

retro-maxillary illumination, when carefully and properly done, is a much better way of lighting up the maxillary antrum, for it does away with any possible impediment to the passage of the rays through the nose. This illumination "by contact" requires a special lamp of about 3.50 to 4 volts, enclosed in a cylindrical metal capsule, which is open on one of its sides, and fixed at the level of the antrum by a metallic arm. The apparatus in the form of a pipe is fastened to the handle of the galvano-cautery, which connects it with a battery of two accumulators, provided with a rheostat. To illuminate the sinus, the lamp must be carried into the retro-maxillary fossa, the posterior extremity of the superior gingivo-buccal furrow, behind the last molar. The furrow is open below and closed behind by a reflection of the mucous membrane from the maxillary tuberosity to the internal surface of the ascending ramus of the inferior maxilla. To give this retro-maxillary fossa its greatest dilatation the mouth should be half open and the dental arches separated anteriorly about one centimetre. The cheek is pushed away from the jaw by a tongue-depressor, so as to expose the last upper molars, and the lamp is passed along the alveolar arch as far as the last molar, the stem being horizontal and the lamp open upward until beyond the malar prominence. The handle is then raised and the lamp enters the retro-maxillary fossa. The cheek is then relaxed, the handle of the instrument is lowered about 45°, the mouth is gently closed, and a slight rotation is given to the arm so as to turn the lamp toward the posterior face of the superior maxilla. The current is then turned on and the examination made. If the sinus is normal it is illuminated, which is indicated by two luminous red spots; a crescentic patch corresponding to the lower lid, and a lower, larger, but less brilliant patch corresponding to the "face jugale" of the antrum. If disease of the antrum be present the illuminated patches are absent.

Treatment: The diagnosis of empyema having been made, the only method which promises a cure is to open the antrum, carefully remove its contents, employ frequent irrigation with an antiseptic solution until pus ceases to be secreted, and then endeavor to close the artificial opening. The best method of operating is that suggested by Luc, and consists in making a large opening in the sinus at the level of the canine fossa. The sinus is then curetted and irrigated with a strong solution of zinc chloride. This large opening is, however, only temporary, and is made to serve a double purpose: first, to empty the sinus of its contents and facilitate the curetting, and secondly to allow of the formation of a free opening between the antrum and the nasal fossa for the purpose of drainage. The latter step of the operation is done as follows: The cheek is pulled away from the superior maxilla; a circular perforator, run by a motor, is introduced and directed against the inner or nasal wall of the antrum anteriorly and immediately above the level of the floor of the antrum. This perforator or trephine has a diameter of 9 mm. In some cases the opening is better made with gouge and mallet. The opening having been made in the inner wall, a curette is introduced through this hole into the nasal cavity, so as to clear away any floating folds of mucous membrane. A short, bulbous-pointed style is then introduced through the same opening, and, its point being guided by the little finger in the nose, it is pushed into the nasal fossa. A strong silk cord is then fastened to the eye of the style, and the instrument is then drawn out in the reverse direction. This pulls the silk cord from the nose into the antrum, and thence out through the buccal opening. To the buccal extremity of this silk cord a drainage tube is attached, and the cord is then again drawn through the antrum and through the opening into the nasal fossa, and out through the nose, and draws the drainage tube after it. This is pulled through until one end of the drainage tube is in the antrum and the other in the nasal fossa. The cavity of the antrum is then wiped dry and powdered with iodoform. The lips of the wound opening into the antrum from the mouth are then closed from behind forward by fine catgut sutures. The antrum should be irrigated several times daily, after the wound in the buccal cavity has throughly healed, with a solution of mercuric bichloride (1:2,000), or a saturated solution of boric acid. The drainage tube may be removed from the fourteenth to the twenty-first day. When the patient uses a handkerchief the antrum is generally emptied during the act. All suppuration from the antrum usually ceases in about six weeks. It is easy to irrigate the antrum, even after the withdrawal of the drainage tube, by means of a short curved catheter. Unless the nasal meatus is kept perfectly healthy, empyema of the antrum is obstinate in healing.

**Tumors of the Maxillary Antrum.**—Pathological neoplasms of the antrum are difficult to recognize if they have not already caused distention of the cavity. The symptoms are pain in the teeth of the upper jaw, a dull ache in the region of the antrum, discharge of pus and blood from the nose in lying down, and more or less epiphora. The pain, which may be in the region of distribution of the infra-orbital nerve, is not apt to appear until the tumor has attained considerable size, and has more or less completely filled the antrum; the distention of the walls of the cavity causing the pain by pressure on the nerve twigs. As the tumor grows, the walls of the antrum are gradually absorbed, and the tumor extends into the nose by extensive enlargement of the ostium maxillare, or through the roof of the antrum into the orbit, or in rare cases through the anterior wall of the antrum into the buccal cavity. When the growth enters the orbit through its floor, the eyeball is displaced upward and outward or upward and inward. These tumors of the antrum gradually extend into all the neighboring cavities. They early involve the nasal meatus, thence extend into the spheno-maxillary and palatine fossæ and pharynx, and finally perforate the base of the skull. They usually involve the orbit later, and sometimes extend into it from the ethmoid cells, even before the floor of the orbit is perforated. In no case is it possible to diagnosticate a tumor of the antrum early in its development.

The treatment of these tumors consists either in extirpation of the growth or in complete resection of the superior maxillary and other bones which may be found diseased.

**The Nasal Meatus.**—The intricate nature of the nasal meatus, with its many folds of mucous membrane, its spongy bones, its intimate connection with all the adjacent sinuses, and its proximity to the orbit, is sufficient cause for the extension of disease from this region to the orbit, and render necessary a thorough examination into the condition of the meatus in all cases of suspected morbid growths. The most common affection met with here is a purulent rhinitis, either independent in itself or secondary to empyema of the maxillary antrum or of the ethmoid and sphenoid sinuses. Prompt curetting of the entire nasal meatus, with removal of the spongy bones in whole or in part, is the only treatment which will lead to a cure. Unfortunately a purulent rhinitis is secondary usually to a purulent process in the ethmoid cells or the sphenoid antrum, and the treatment must be primarily directed to these cavities.

Polypoid growths in the nose may extend into the ethmoid cells and produce secondarily many of the symptoms of orbital disease. These growths ofter

possess a partly cartilaginous consistence. It has never been definitely determined whether all the visual defects met with in connection with polypi of the nasal meatus are caused by pressure of the after-growth on the optic canal or in the ethmoid cells, and thence against the inner wall of the orbit. Whatever the cause, the loss of vision is due to pressure on the optic nerve.

**Tumors of the Nasal Meatus.**—Tumors of the nasal and pterygo-palatine fossæ may enter the orbit through the infra-orbital fissure. They cause neuralgia of the infra-orbital or posterior alveolar nerves. The orbital portion of the tumor may divide into two branches; one involving the orbit, and the other extending into the cranial cavity through the supra-orbital fissure. They eventually extend into all the neighboring cavities.

In the treatment of these growths, it is absolutely necessary that they should be completely extirpated early in their development, together with all the surrounding tissues, including the bony walls of the cavities involved. If a malignant tumor has already invaded the deep bones of the face and base of the skull, including the cavities contained within them, the case may be regarded as hopeless, and while an operation may relieve the patient temporarily, it undoubtedly hastens the fatal termination.

**Diseases of the Ethmoid Cells.**—The cells of the ethmoid form a pneumatic labyrinth which increases in width from above downward. The ethmoid anteriorly is connected with the lacrymal bone, and posteriorly often with the orbital portion of the palate bone. The posterior ethmoid cells and the sphenoid antrum open into the superior nasal meatus. In rare cases the ostium maxillare is absent, and the maxillary antrum communicates with the ethmoid cells and sphenoid antrum. Occasionally the lateral ethmoid cells project markedly toward the orbit.

The symptomatology of disease of the ethmoid labyrinth is always perplexing, and a diagnosis is thus rendered extremely difficult. In inflammation of the ethmoid cells, positive subjective symptoms are wanting. In mucocele the symptom is a gradual, painless development of a tumor on the inner wall of the orbit, which later shows signs of fluctuation, and the eyeball is displaced forward, outward, and sometimes downward. Until fluctuation appears, it may be confounded with an osteoma growing from the inner wall of the orbit. Puncture or incision of the tumor will decide the diagnosis. Ectasia of the ethmoid cells occurs mainly in young persons. From a cosmetic standpoint these cases should be treated early in their course, before the ectasia becomes too large; for in the latter case the posterior part of the orbital wall cannot be replaced, and there is more or less deformity. In empyema of the ethmoid cells, whether acute or chronic, the periosteum suffers also, and this may lead to necrosis. In caries of the lamina papyracea, the subjective symptoms are dull pain, increased by pressure in the neighborhood of the diseased bone and vertigo. Redness of the lids at the inner canthus may be present. A hard tumor may be felt at the inner canthus, and later occur fluctation, strabismus, diplopia, exophthalmos and limitations of motility of the eye, and impaired vision. Pus found in the region of the middle turbinated bone must come from the posterior ethmoid cells. If the empyema is of an acute character, symptoms will appear in the nasal fossæ and orbit, such as difficulty of respiration through the corresponding nostril, a nasal tone to the voice, more or less epistaxis, and headache. If no relief is given by way of the nasal fossæ, the disease will invade the orbit and cause the symptoms above mentioned. If the empyema be chronic, the ectasia of the labyrinth may be confounded with a neoplasm in the ethmoid.

The etiology of empyema of the ethmoid is obscure, sex and age seeming to exert no influence. The nasal fossæ contain a large number of microbes, which may easily enter the ethmoid cells and there multiply and set up an inflammatory process. Traumatism of the nasal and orbital bones may also set up an empyema. The primary cause of such inflammation is the presence of some infecting agent, which sets up an irritation, and causes a thickening of the mucous membrane of the labyrinth, which subsequently ulcerates and exposes the bone. This becomes carious, with the formation of sequestra, and the labyrinth is destroyed, or, if the process is not destructive, neoplastic tissue is formed with thickening of the wall of the ethmoid cells and exostosis.

Transillumination as a means of diagnosis in disease of the ethmoid cells is uncertain and perhaps dangerous. It is uncertain because anatomical anomalies exert an effect on the transmission of light. It is dangerous because it may lead to unjustifiable operations. The sinuses may vary both in shape and dimensions, not only in different individuals, but also from one side to the other in the same person. As abnormal sinuses are more numerous than typical cases, transillumination cannot here render any great service. It may help to confirm a diagnosis already made, but it should not be relied upon.

Treatment: In all cases of empyema, the cells should be opened, the pus evacuated, and all fragments of carious bone should be removed. A free opening should be made through the nasal meatus into the ethmoid cells with a curette, and if the swelling has presented in the orbit, it should be freely incised through the conjunctiva, and free irrigation from the orbit through the ethmoid and into the nose should be carried out. A drainage tube should then be introduced from below upward into the ethmoid cavity, and daily irrigation should be kept up until all discharge ceases.

**Tumors of the Ethmoid.**—Neoplasms of the ethmoid are usually of the sarcomatous or myxo-sarcomatous type, though occasionally other varieties are met with. A morbid growth confined within the ethmoid cells gives rise either to no symptoms at all, or merely to headache, paroxysmal in character. The orbital symptoms are the same as those of tumor of the orbit. The motility of the eyeball is limited. The vision may be slightly affected, or there may be complete blindness. The visual field may not be involved. If the tumor has entered the nasal meatus, the mouth is more or less open, the speech is nasal, and later there is loss of the sense of smell. There may be more or less dropping of clear fluid from the nose, even in the case of solid tumors, owing to a communication between the upper wall or roof of the ethmoid cells and fissures at the base of the skull. There may also be orbito-palpebral emphysema, and hemorrhage from the nostrils on one or both sides.

Enchondroma of the ethmoid is very rare, and always starts from the base of the skull.

Polypi originating in the ethmoid cells and confined within these limits are relatively rare, but nasal polypi usually start from the ethmoid. Polypi of the nasal meatus may conversely penetrate into the ethmoid labyrinth.

Fibroma originating in the ethmoid has been observed but once.

Osteoma of the ethmoid usually begins in some neighboring cavity, and the first objective symptom is a very hard tumor just behind the inner canthus, which is followed by exophthalmos and diplopia. The tumor also usually involves the nasal meatus. The vision may be normal or impaired. There may be papillitis of the optic nerve, and suppuration of the cornea from inability to close the lids completely

over the eye. If an osteoma be encapsulated, it may easily be separated from its bony attachments. These osteomata never tend to penetrate the cranial cavity, and their operative removal is not, as a rule, difficult. The only treatment for tumors of the ethmoid bone and cells consists in their radical removal. Further remarks upon the kind of surgical interference and its prognosis will be found at the end of this paper, to which special attention is invited. The surgical attack should always be made through the orbit.

**Diseases of the Sphenoid Antrum.**—Some curious anomalies are often met with in the sphenoid bone. The anterior, posterior, and lateral walls of the antrum are sometimes very thin. The anterior wall may be entirely wanting, and then the sphenoid antrum opens into the ethmoid cells. The anatomical relations between the ethmoid and the sphenoid are so intimate that any chronic process starting in either bone is almost certain to involve the other at a comparatively early date.

The subjective symptoms of empyema of the sphenoid antrum are the same as those of empyema of other neighboring cavities, though the headache is located at the back of the head, and the ocular lesions are either purely functional or affect the optic nerve back of the eyeball. Disease of the body of the sphenoid, whether ending in caries or not, may cause not only exophthalmos but also disturbance of vision, on account of the close proximity of the optic canal. Pain occurring in the course of disease here may show itself in a totally different part of the area of influence of the trifacial nerve, and thus lead to a faulty diagnosis. Attempts have been made to treat the interior of the sphenoid antrum through the nose, but the position of the opening into the nose is so variable, and the use of the rhinoscopic mirror is so unsatisfactory, that such attempts have usually been abandoned. Transillumination is of no practical value here in assisting us in a diagnosis. Inasmuch as the ethmoid cells are usually involved in abscess of the sphenoid antrum, if entrance through the nose proves futile it is better to open the ethmoid through the orbit, clean out the contents, and then penetrate the sphenoid antrum and thoroughly curette its interior.

**Tumors of the Sphenoid.**—So long as a new growth is limited to the sphenoid antrum, either the subjective symptoms are entirely absent, or there may be severe pain in the head, usually in the occipital region. If the process extends to the adjacent structures, symptoms arise which point to the probability that the sphenoid bone is the seat of the disease, such as blindness due to compression of one or both optic nerves, and the visible or tangible presence of the growth in the nose, ethmoid, orbit, or skull. The entrance of the growth into the cranial cavity may occur without any subjective symptoms, or there may be sudden, severe headache. If the progress of the growth is very rapid, meningitis or cerebral abscess will result. The ophthalmoscopic symptoms are either papillitis or atrophy of the optic nerve due to perineuritis and pressure of the swollen nerve-sheath on the optic nerve fibres. In some cases the pressure is exerted on the nerve in the optic canal. Tumors here may perforate the middle fossa of the skull without causing blindness. If an orbital tumor rapidly causes blindness, and the latter starts from the temporal side of the field and leaves the region of the macula lutea unaffected to the last, and if at the same time a growth appears in the nose, it is probable that the tumor began in the sphenoid antrum.

Polypi may develop in the antrum independently, and may penetrate the roof and enter the middle fossa of the skull, and even cause meningitis, without giving rise to any disturbance of vision.

Osteomata of the sphenoid are sometimes developed from the embryonic remains of cartilage. They tend to penetrate the cranial cavity, and by compression of the optic nerves in the optic canals early lead to blindness of both eyes. The same symptoms may also be produced by hyperostosis and exostosis of the sphenoid.

Enchondroma and carcinoma of the sphenoid are exceedingly rare diseases.

Sarcoma is by far the most frequent morbid growth met with here. In sarcoma of the base of the skull it is exceedingly difficult to determine the point of origin. The general symptoms are loss of sight, hearing, and smell in the order named; facial paralysis and neuralgia, vertigo, somnolence, vomiting, loss of memory, hemiparesis, and loss or impairment of speech.

A few words in conclusion in regard to neoplasms of the deep sinuses of the face. Extra-orbital tumors originating in the bones or sinuses adjacent to the orbit form a class of cases which are the most serious and desperate of all. The prognosis in these cases must be regarded as absolutely bad from the beginning. No matter where the growth originated, all the deep bones of the face and their communicating sinuses eventually become involved. By emptying the sinuses and extensive exsection of the diseased bones, we do not succeed in arresting the progress of the malady, and subsequent operations become necessary, which sap the strength of the patient and weaken his powers of resistance. The tendency of these malignant tumors is to grow forward or outward rather than inward or backward, and this fact probably explains why patients afflicted with such tumors live as long as they do, and why they usually die from exhaustion rather than from extension of the growth to the brain. The tendency to extension outward and forward of these tumors may perhaps also explain the increased rapidity of their growth after exenteration of the orbit, or after the more radical operation of exsection of the diseased bones. The empty orbit is a free space toward which there is no resistance to the extension of the neoplasm, while backward or upward its progress is hindered by a bony wall of varying thickness, in which absorption goes on slowly, even when the periosteum has been removed. Three years ago I presented to the American Ophthalmological Society the following conclusions on this branch of the subject, and my experience since has led me still further to emphasize their importance:

1. The prognosis of all forms of malignant orbital tumors is unfavorable; and if the tumor is primarily one of the deep facial bones or their sinuses, the prognosis is positively bad.

2. With the single exception of encapsulated tumors of the orbit, surgical interference is almost invariably followed by a return of the tumor, and the growth of the secondary tumor is more rapid than that of the primary lesion. With each succeeding operation the period of quiescence in the return of the tumor grows shorter and the rapidity of the growth increases.

3. The patient's family, and in certain cases the patient himself, should in the beginning be told of the serious nature of the trouble, and be warned that complete removal of all the diseased parts is a hopeless task. The burden of the decision as to surgical interference must rest upon the shoulders of the patient.

4. Repeated operations in these cases undoubtedly shorten the life of the patient. While it is our duty, therefore, to operate in all cases in order to relieve severe or unbearable pain, we should be slow to operate merely for the sake of relieving temporarily physical disfigurement or deformity, especially if we are convinced that by so doing we shorten the life of the patient, even if that shortened life is rendered more bearable.

# SOME REMARKS ON CHRONIC BRIGHT'S DISEASE.[1]

BY ARTHUR R. ELLIOTT, M.D.,

CHICAGO,

PROFESSOR OF URINARY DISEASES, POST-GRADUATE MEDICAL SCHOOL.

THE term "chronic Bright's disease" in its full generic sense includes several more or less distinct pathological states. When the term is applied as a specific appellation to denote a single diseased condition it is chronic interstitial nephritis that is meant in preference to its congeners, chronic parenchymatous nephritis, and amyloid or cyanotic kidney, these latter states being in the main associated with antecedent or coincident morbid processes. In this manner the name "chronic Bright's disease" has been employed in the title of this paper to denote chronic interstitial nephritis or granular kidney, the latter a term much in vogue among English clinicians, although less frequently used in America. Some question may be raised against the use of the two as synonymous terms, the name "granular kidney" denoting a process purely cirrhotic in nature, while "interstitial nephritis" implies the occurrence of inflammatory changes. This distinction is of greater theoretical than practical interest, for the end product of the two is the same, the clinical history is almost identical, and I believe it rare indeed for a purely cirrhotic process to run its course without the occurrence of incidental inflammatory changes.

Chronic interstitial nephritis is a disease of frequent occurrence, a frequency by no means adequately recognized. Various statistics have been compiled from post-mortem records, which go to show, according to West, an occurrence of from eleven to eighteen per cent. This is largely in excess of its clinical recognition. Goodhart's statistics compiled from the records of Guy's Hospital yield fifteen per cent., while the records of the Birmingham General Hospital are represented by Saundby as revealing a frequency of eighteen per cent. The observations published by Samuel West in the last Lettsomian lectures are still more striking and suggestive. Under his direction an investigation was conducted to show the cause of death in persons brought into St. Bartholomew's Hospital dead or dying, a total of seventy-nine cases being examined, in all of which a post-mortem examination was made. The results of this inquiry revealed the remarkable fact that in forty-eight per cent. chronic interstitial nephritis was present. In 16.8 per cent. it was the only demonstrable cause of death, and in 21.6 per cent. more it played its part either in producing death or causing the lesion which led to death—that is, together 38.4 per cent. If greater weight of evidence was necessary to establish the frequency of this lesion, it is furnished by the table compiled by Mahomed in an endeavor to determine the relative frequency of granular kidneys to healthy kidneys at different age periods; three hundred and thirty-six cases were examined, fifty-seven of which were over fifty years of age:

| Ages. | Granular Kidneys Found in— |
|---|---|
| 10–20 | 2.3 per cent. |
| 30 | 3.0 " |
| 40 | 12.0 " |
| 50 | 38.5 " |
| 60 | 43.0 " |
| Over 60 | 50.0 " |

Could more striking proof be furnished of the frequency and hence the importance of this affection? Its interest does not depend upon its frequency only, but its insidious course and elusive manifestations render it one of the most interesting clinical problems. It is a common cause of sudden death, and, as shown by West, is often found post mortem when not suspected. It is many times overlooked in cursory examination of patients, and may as frequently be unexpectedly revealed by careful examination. Moreover, by virtue of its great frequency it is often associated with other diseases, and it introduces a grave element into their prognosis. I shall make no attempt to consider this interesting condition in anything like a thorough or co-ordinate manner, but shall simply touch upon a few of its aspects which an increasing experience has impressed upon me.

Granular kidney has been called a disease of middle life. It is true that it is most often recognized during that epoch, but it may have existed for years and have had its origin in early life. It is an essentially chronic process, indeed one of the most chronic of all affections, extending over a period of years often ten, fifteen, or even twenty in number. In the vast majority of cases it is not during its early stages that its presence is discovered, but only after the morbid changes have so far advanced as to interfere decidedly with the functional capacity of the kidneys. This is mainly due to the fact that until that point is reached no symptoms referable to the kidneys as the seat of trouble are apparent, and also partly, I am satisfied, to an insufficient appreciation of the elusive early symptoms of the disease, for at no time in its progress will careful examination fail to elicit evidence of its existence. A beneficent nature has endowed the human organism in essential places with organic provision sufficient to meet any reasonable degree of strain above the physiological level that may be imposed upon us by the exigencies of life. Accordingly we are provided with lung tissue largely in excess of the capacity for aeration necessary in ordinary physiological living, so that we are enabled without difficulty to meet emergencies, and so it is that extensive organic impairment of lung tissue is compatible with a fair degree of health and usefulness. We see this admirable arrangement duplicated in the kidneys —organs which are even more abused than the lungs, even more frequently called upon to protect the system from the results of our excesses. It is certain that there is a far greater supply of renal gland tissue than is ever required in physiological living, and which can be dispensed with without discommoding the individual so long as ordinary conditions prevail. The degenerative changes which are the special feature of the granular kidney advance very slowly and may exist months and even years before the renal tissue has been so far encroached upon as to render the organs incapable of the proper performance of the work demanded by normal conditions. It is then only that a distinct and unequivocal symptom complex becomes apparent. Ralfe indeed states that it is only when two-thirds of the kidney substance has been destroyed that toxæmic symptoms become prominent. When this point is reached the symptoms of a chronic advancing uræmia combined with distinct urinary abnormities render the condition very easy of recognition, but, unfortunately, by this time the period for usefulness has to a large extent gone by, and all that remains is to compromise with existing conditions, conserve the badly damaged organs, and prolong an existence often miserable enough. Such a point is not usually reached until years after the degenerative lesion was first originated. If by good fortune the disease is discovered in its incipiency, before the organs are greatly hampered, a very promising field is open to our endeavor, and by judicious management further advance may be arrested or so far retarded as to enable the patient to live in comfort and usefulness many years. Our attitude toward the disease must not be one that regards it as a purely renal lesion. Pri-

[1] Read before the Illinois State Medical Society, May 16, 1899.

marily it may be so, but it soon becomes much more than that. The changes accompanying its development are widespread, seriously involving the circulatory organs and disturbing many of the systemic functions.

It is not too much to say that the majority of cases of chronic interstitial nephritis are never discovered, and that apoplexy and heart disease frequently usurp its rightful place upon mortality records. This is not because the diagnosis is difficult, but because there is little in the symptoms to draw attention to the kidneys. The initial stages of the disease present the greatest difficulties to a precise diagnosis, and it is this phase I would discuss. The early symptoms are indefinite and not such as to excite the alarm of the patient, so that the physician is seldom consulted until the disease is well advanced. If the patient seeks early advice it is usually for the relief of some symptom not referable to the kidneys. Opportunities will always exist and frequently arise that will enable us, if our attention is awake to the significance of certain alterations, to discover the disease. Thus granular kidney is the special condition which is likely to be accidentally revealed by examination of the urine for life insurance. Likewise the systemic disturbance of acute febrile disorders may intensify latent symptoms so as to lead to its discovery. Many an obscure nervous, circulatory, or digestive condition in the middle-aged will become easy of interpretation in the presence of a thickened artery, heightened tension, and polyuria. The frequency of this degeneration during the latter half of life certainly warrants an invariable analysis of the urine whenever obtainable, although there may seem no special indication for it.

The symptoms of chronic interstitial nephritis fall into two groups; those referable to the kidneys and those arising from alterations in the circulatory apparatus. The renal symptoms are as a rule much more tardy and latent than the cardio-vascular. When present during the earlier stages they consist of a moderate polyuria principally nocturnal, an inconstant albuminuria, and reduction of urinary solids. The only urinary symptom at all constant during the early stages is polyuria. This is not excessive or troublesome, and is usually more noticeable at night-time, compelling the patient to rise one or more times to relieve the bladder. This symptom is of easy and gradual onset, and, unless extreme, is accepted without concern by the patient, who usually does not regard it as peculiar, but on the contrary may look upon it as favorable to pass so much urine, and it may require close questioning to determine its duration. When no vesical or prostatic cause exists to account for the symptom, its presence as an acquired habit in people of middle age is extremely suggestive of commencing granular nephritis. Aside from this manifestation, the renal symptoms are the latest to develop, and we must perforce depend upon physical signs for our diagnosis. These are referred to the circulatory apparatus, and are the evidences of cardiac enlargement, thickened arteries, and high arterial tension. Cardiac hypertrophy is a pretty constant accompaniment of granular kidney, Goodhart's post-mortem average being 89.6 per cent., Ewald's 84 per cent., and Kanthack and Holmes' 90 per cent. A displaced and forcible apex beat together with alterations in the cardiac sounds usually furnish an easy clew to the ventricular hypertrophy, although it is by no means uncommon for it to exist in moderate degree and yet be impossible of demonstration. The vascular condition is more easily demonstrable as a rule and is perhaps more constant. The arteries are felt to be hard and not easily obliterated by pressure, full between the beats, and feeling like fibrous cords underneath the examining finger. At the same time the arterial tension is persistently raised, as can be readily perceived by the finger, or demonstrated by means of the sphygmograph. Accentuation of the second cardiac sound in the aortic area is an invariable accompaniment of increased arterial tension. A persistently raised arterial tension is one of the most suggestive evidences of interstitial nephritis, and when combined with thickened arteries is most frequently the earliest manifestation of the disease. Mahomed's view, since supported by Goodhart and recently agreed to by West, was that these were the early initial stages of granular kidney. This combination of conditions occasionally gives rise to a symptom which may be the first positive declaration of the disease, and its occurrence is full of suggestiveness. I refer to hemorrhage. This most often takes the form of an obstinate epistaxis arising spontaneously or following exertion such as coughing, lifting heavy weights, or straining at stool. Less frequently apoplexy, subconjunctival hemorrhage, hæmatemesis, hæmoptysis, and hæmaturia occur. Within my recent experience the discovery of the renal lesion has been due in three instances to epistaxis, in one to hæmoptysis, and in another extremely interesting case to severe spontaneous renal hæmaturia. Although hemorrhage may constitute the symptom that first leads to diagnosis, in the majority of such cases the disease is well advanced. Hemorrhage occurs most frequently in patients beyond middle life in whom some degree of arterio-sclerosis is present, but even in the young granular kidneys must not be disregarded as a cause of repeated epistaxis.

During the initial stage of the disease the changes in the urine, although characteristic, are in the majority of instances extremely difficult of satisfactory demonstration. Albuminuria is slight, often amounting to but a faint trace with the most delicate tests, or it may be absent altogether. When present it may vary much in amount at different times, or may disappear entirely for considerable periods. It may be so elusive as to require the analysis of several specimens to discover it, and in rare instances it may be absent during the entire progress of the case. It frequently assumes a cyclic character, appearing in the urine of activity or after eating, and entirely disappearing in the urine of quiescence and recumbency. It is clearly evident from its inconstant character that too much significance is not to be attached to its absence. We must not, however, allow its occasional absence to detract too greatly from the value of albuminuria in the diagnosis of interstitial nephritis. It will always be a symptom of such import, especially when found in the urine of patients of middle age, even if its amount is slight and its occurrence irregular. The specific gravity is in most instances persistently reduced several points below the normal, and, curiously enough, conditions such as vomiting, diarrhœa, and profuse perspiration, which ordinarily cause concentration of the urine, do not have the effect of raising the density to the normal standard. Volumetric analysis of the collected twenty-four hours' urine will reveal a diminution of urinary solids, especially of urea. The microscopic findings are singularly elusive, and it may require the most painstaking search of the urine sediment to reveal anything abnormal. Hyaline casts can usually be detected if the centrifuge is used and proper illumination is employed. They are sparse in number, exceedingly light in texture, and extremely difficult of detection except in highly centrifugalized sediments. With a urine so nearly negative in comparison with the usual standard of pathological variation, many instances of the disease must inevitably escape detection unless we depend upon other means than the urine for our diagnosis, or combine with our urinary findings the information elicited by physical examination. We must dismiss from our

minds the belief that the presence of albumin and casts in the urine is essential to a diagnosis of nephritis, and cease from attaching any negative inference to the results of the analysis of a single specimen. We must impress firmly upon our minds the value of a thickened artery, and be alive to the significance of a heightened tension. In general but two things can result in thickened vessels and increased tension, and they are atheroma and interstitial nephritis. If the former element can be eliminated we should search well to confirm the latter; indeed, we should investigate all cases, for atheroma and granular kidney frequently coexist. With our consciousness awake to the special significance of such manifestations even if present in but moderate degree, and with our minds disabused of belief in the overwhelming importance of urinary findings, I am sure much greater certainty of conclusion will result, and many more cases of granular kidney will be revealed and at a period while still amenable to treatment.

I have been much impressed by the influence of the hereditary element upon the prognosis of this affection. The hereditary character of interstitial nephritis has attracted the attention of many observers, and numerous records have been made of cases occurring in different members of families. The annals of every one's practice will sooner or later furnish instances of this hereditary association. Curiously enough, the risk to the offspring of those who have died of Bright's disease is practically ignored by insurance companies. This hereditary predisposition as an etiological factor is regarded in a very conservative manner by writers upon the subject. I believe it to be a much more important element than is generally credited, and a far more frequent one. It is true that it is impossible save in a few instances to elicit a direct history of Bright's disease, but it must be borne in mind that many, perhaps the majority of cases, of granular kidney are never identified as such, and that apoplexy, heart disease, gout, dropsy may be the various aliases under which the disease in former generations has masqueraded. I believe it a significant fact to elicit a history of any one of these as a family complaint. It may seem but a matter of clinical interest thus to trace a relationship between a present nephritis and a former apoplexy, but it has far greater importance than the satisfaction of clinical curiosity. My experience leaves me in no doubt that an inherited vice of constitution plays a most insidious and disastrous part in the progress and termination of interstitial nephritis. Such cases bear no mark of identification to distinguish them from others save in their more rapid downward course and greater resistance to treatment. Not only will the clinical manifestations in cases marked by an inherited taint be found more unyielding, but our utmost efforts may fail of the happy results obtained in the non-hereditary type, and comparatively little influence be exerted in staying the progress of the degenerative changes. I do not mean to imply that the course of such cases is a rapid one toward a fatal termination, but rather that they are much less readily influenced in a favorable way by dietetic and other measures, and that their course is more unfortunately eventful and more uniformly progressive.

The obstinacy to treatment that these cases present is all the more remarkable because we are dealing with a disease which in its early stages responds in a flattering manner to treatment. It is surprising that so little note has been taken of this influence in prognosis, for I can find no reference to it in the literature at my command. Our forecast must be a conservative one when it is a feature of the case.

**The Water Supply of Brooklyn** is so short that it has been found necessary to stop the public fountains.

## PREPARING FOR THE KNIFE IN EUROPEAN HOSPITALS.[1]

By J. PRESTON MILLER, M.D.,

WASHINGTON, D. C.

SINCE the rise of the present dynasty of micro-organisms, surgery has been revolutionized and perhaps more greatly benefited than any branch of medical art. Nowhere has this change been so pronounced as in the preparation of patient, operator, instruments, and surgical accessories, all of which is more elaborately done in Europe than America—England excepted.

I shall here relate in part how I found these things done in twelve cities of Europe, every one of which is noted for achievements in surgery, and some are pre-eminently medical centres of Europe.

My longer sojourns were in Vienna, Berlin, and Paris; while London, Brussels, Heidelberg, Munich, Budapest, Prague, Dresden, Leipsic, and Hamburg were more briefly visited—all done within a year, and including the teaching and operating season, 1897–98.

The positions in hospitals are radically different from ours when under government control and support. The operator-in-chief is usually spoken of as director of the clinic. He is paid a salary, and often given a residence specially built for him, attached to the hospital or detached, but in the hospital grounds, with telephonic communication whereby he may be called at any hour. This is especially true of directors of hospitals for diseases of women, in which there are always obstetric wards, constituting indeed the larger part of the hospital. The provision for these doctors is not unlike that of ours at insane asylums, except that the European's tenure is not subject to mutations of politics.

Internes and assistants are in evidence galore, all being provided for within the building. The former depend upon excellence at competitive examination for their position, while the latter are said to have a "pull" with the director. All are paid salaries, but assistants receive from three to eight times as much as internes, thus: If the first assistant gets 800 gulden per annum, the second assistant is paid 600, the third assistant 400, the ungraded assistants 300, while the internes have 100 gulden. On the professional card of every assistant is stated his position, to whom he has the honor of being assistant, though the grade is omitted except in case of the first assistant, when that is also set forth on the card.

Graded assistants are permitted to give special courses to students and doctors, which at Vienna pays in some cases 2,500 gulden or more yearly. Assistants when in the hospital two years begin operating, and those having grades take turns at filling the place of the director when the latter is absent. Some of these have served under the same director ten or twelve years, and not only carry out his technique, but even excel him in dexterity at the knife.

Directors usually enjoy the favor of royalty, and if the patient happens to be a gravid empress or queen, the doctor is required to keep from contact of any and all other patients for thirty days before and after partura, and make daily visits to the palace, where at times even the sacred larder is thrown open and he dines and wines with H. R. H. But we must return to the hospital, though the director is often away!

It is claimed for these hospitals, with their ample material, commonwealth support, and life-tenure scientists, that they lead in the development of things of the greatest value to medical progress. It is true, the Teuton is by temperament toilsome—patient in the tedium of the most minute detail of research, and accurate in the employment of methods by which he dis-

[1] Read before the Medical Society, District of Columbia, Washington, D. C., April 19, 1899.

covers that a thing is and what it is, be it never so microscopic. But what to do about it, to turn it to practical account is not always best determined by him, more especially if he is a life tenure. The practical features of the private hospitals abroad suggest that the motto, "Private enterprise superior to public management," may obtain in other things than ownership of railroads.

At Hamburg the Eppendorf [1] is the public hospital. It has eighty buildings, eighteen hundred beds, more than two hundred nurses, twenty-six internes, and seven directors. Of the latter, Kümmel, Sick, and Graff are surgeons. There are three operating-rooms in the operating-building: one for males, one for females, another for laparotomies. The first case in this, the first European hospital visited, was a shapely young girl, wheeled into the rear of the operating-room, farthest from instruments and the light. She had a folded towel over her eyes, and was clad in a single garment, fashioned somewhat like a bath robe, which was thrown back, giving the effect of a white sheet, on which she lay nude, except the sleeved arms, while the examination was made by Kümmel and two assistants. When she was interrogated by the doctors she would take hold of one end of the towel and gradually lift it while assistants brought the edges of the garment together, but the answer from her came not until this had been snugly done and the towel completely lifted from the eyes. She spoke only when looking her interlocutor fully in the eyes. When questioning ceased she herself placed the towel over the bridge of the nose, and the examination proceeded as before. She was chloroformed before being moved forward to where the instruments and light necessary for the operation were. It was an Alexander operation, and the only one I witnessed while in Europe.

Patients for abdominal section are given a bath the day before operation, then shaved and scrubbed, after which a cloth saturated with sublimate solution, 1 to 1,000, is applied over the abdomen by bandage until the time of operation, when it is removed and green soap with sand applied with a handful of wooden fibre. This soon gives an excellent lather, and has the merit of being used but once, when it is thrown away. After the soap is washed off, alcohol is applied, and lastly sublimate, 1 : 1,000.

The hands of the operator and those assisting are prepared in the same way, except that individual brushes are used, all having separate stationary wash-bowls. When in doubt about whose brush it is, it is thrown away and a new one brought. Five-minute sand-glasses are at the hydrants, indicating the required time for scrubbing the finger nails with soap, though these are no longer used strictly as formerly. Next, alcohol from a large vessel is forced into a small glass tray by pressing a rubber bulb with a pedal attachment, this being the measure for each one assisting, and is used without the hand touching anything except alcohol. Lastly, sublimate solution is used with a brush.

Kümmel uses chloroform almost entirely; ether rarely; and mixture of one with the other, or any drug whatsoever with either, never. Bad effects from iodoform have been witnessed, and Kümmel is chary of its use. Sulphonal is a constituent of the new drug, loretin, which has replaced iodoform, being used in septic cases, while sterilized gauze is used in cases surely clean. Chromicized catgut is tabooed; Kümmel assures me it is not absorbed. Catgut is placed in a four-per-cent. formalin solution for twenty-four hours, then boiled one-half hour before being placed in alcohol, where it remains until used. Fine silk sutures, I am told, are absorbed almost as readily as catgut, and are freely used intramurally. Animal sponges are completely replaced with gauze. Instruments, lying in their solutions, are at the side of the operator, who reaches his instruments and threads his needles himself, the needles having springs instead of eyes. Drainage is by glass tubes with lateral openings, when gauze is not suitable—no rubber. Short rubber boots easily kicked off after operation, without the use of the hands, cover the shoes of all assisting at operations, who are further clad in linen overalls, short-sleeved undershirts, and long rubber aprons; no covering over head, hands, or arms.

Visitors are required to wear long linen gowns, reaching to the feet and buttoned from the chin down. Surgeons and internes wear these same white robes in walking around over the grounds to the various pavilions and through the wards.

Prochownik has a large, three-story building of his own in the centre of the city for a gynæcological clinic. It has twenty-four beds, two resident and two volunteer assistants. It has pathological and bacteriological rooms, and separate operating-rooms for major and minor operations. Having a large practice in Hamburg, he has regular hours only for this hospital. Cleaning is much as was seen at Eppendorf, but he has wash-bowls fixed in iron frames on casters, which he shoves around with his foot, and by pedal attachment turns water off and on, hot or cold, without use of the hands. Likewise the various fluids, sterile or chemical, and hot water for plastic operations, are controlled by the foot of the operator. Large glass tanks on shelves have rubber tubes, metallic bars clamping the tubes with springs near the surgeon, which open when the foot presses the pedal. I saw Prochownik do a Hegar operation with the assistance of only one person in the room, and that a female nurse. He maintains that before he can make an assistant understand what he wants he can help himself. He seldom gives a general anæsthetic for plastic operations on the perineum or pelvic tracts, because of the danger of strain on the sutures from vomiting. He infiltrates with Schleich's solution, having a piston syringe holding an ounce, and uses all of this before beginning with the knife. The vagina is cleansed with soap, douche, gauze, and the use of the hand; no brushes are used for this purpose at Hamburg.

At Berlin v. Bergmann is easily the foremost surgeon. He is professor in the university and director of the largest clinic; more than twenty thousand surgical cases being treated annually in the public hospital over which he is chief. Of these, perhaps three thousand come to the department under his personal visitation. Only the grave or difficult cases are selected for this great surgeon. The material is not from the city of Berlin alone, but from the kingdom of Prussia, which supports and is benefited by this charity. He operates in an arena of an amphitheatre seating about two hundred students, with usually half as many more standing behind the seats and seated down the aisles. There are usually eighteen assistants cleaned for action and lined up in the shape of a V, with its base a little in advance of the operating-table and on either side; and when one is of the favored few admitted to the arena, one is reminded of a football team when entering from the rear toward which the apex of the lines point.

After the cutting and most important part of the suturing have been done by v. Bergmann, the table containing the patient is shoved back, where the suturing is finished, and the drainage and bandages are adjusted by assistants in waiting, guided by at least one of the more advanced ones, who has had a hand in the operation from the beginning and has been given points from v. Bergmann as to finishing. Some days six or eight op-

[1] *Vide* "The Different Fields of Operative Surgery and Gynæcology in Europe," by the author, MEDICAL RECORD, March 12, 1898.

erations are done, when the whole line of assistants is utilized. The hours are from 2 to 4 P.M., but usually extend a half-hour or more beyond the time fixed.

Cleansing the field of operation is done with ordinary white soap, shaving, washing off the soap, then with alcohol, and lastly sublimate solution, 1 : 1,000. The operator and all assisting apply the same process, except razor, on the hands and arms. Sterilized gauze is handed out of tin sterilizers by female attendants, with long, white, cotton gloves, sterilized. All other hands and heads are uncovered. Iodoform gauze is freely used in all septic cases; the sterilized in aseptic ones. Catgut is prepared after v. Bergmann's method, as given in any modern work on surgery.

Female nurses attend at hernia operations on the male the same as at tracheotomies, and find them of such absorbing interest that their eyes are not always on the instruments which they hand to the operator. I remember alarming results occurring to Bergmann one day, when a scalpel was handed him point foremost, when the operation had been well along, his hands covered with blood and inflammatory exudate, the instrument going deeply into his finger. Though Bergmann immediately used surgical measures to prevent serious results, we received daily reports that he was suffering from blood poison, creating widespread and deep concern, until we saw him again about ten days later.

Olshausen is director of the Königliche Frauenklinik, with its immense material. Cleansing here does not differ materially from Bergmann's system. Iodoform is dusted over surgical wounds within the abdominal cavity, as everywhere else, as soon as the sewing is completed and the surface dried; being applied with a powder blower. Iodoform gauze is freely used, and catgut prepared after Bergmann's method. There is a separate room for laparotomy. Chloroform is the preferred anæsthetic.

Nagle conducts the woman's clinic in the great Charité, with no wide difference from Olshausen. Catgut is everywhere used in Berlin, and I believe is always prepared according to Bergmann.

Schleich, Dührssen, Mackenrodt, Landau, and Martin all have interesting private clinics, but less elaborate in the number of assistants, and having much in technique that differs from what we have seen.

Martin is noted for the fixed flat table named after him — opposed to Trendelenburg. In this I found him without following among German surgeons—Zweifel and Winckel excepted. Martin no longer uses the spray as formerly on visitors as they enter the operating-room, then continuing its use over the door while the operation lasts. The patient is shaved and washed outside the operating-room. The entire perineum is shaved for laparotomies, while other operators of Berlin shave only the pubes and then cover the perineal and pubic regions with antiseptic or sterile cloths. Martin's patient is entirely nude. The operator sits at the foot of the table, and brings the patient to him until the perineum is quite even with the edge of the table, if not projecting, the legs unsupported and dangling. He wears a rubber apron, which frequently presses the perineum during laparotomies, which he does sitting. During operations he reaches around and moves his stool with his own hands, and places them on the table and other furniture without cleaning before continuing the operation, but this furniture looks as if it had been scrubbed with sand that morning, being all wood. He has only one assistant at the operation, besides one female nurse; the former is occupied chiefly in preventing protrusion of the intestines, while the nurse brings things within arm's length of the operator, who reaches for what he wants himself. The patient, having been chloroformed outside, is brought in and laid upon the table, when she is seldom given chloroform during the operation. Tumors two or three times the size of a man's head are not unusual. In three minutes from the time Martin's knife touched the skin of the patient the tumor was in a bowl on the floor by the side of the table, when I timed him at the first operation I saw him do. He sews up the cavity with one long suture, as if continuous, but his assistant follows with the scissors, cutting proper lengths for tying without delay to the operator. Martin depends more upon the speed with which he closes his wounds than strict compliance with modern requirements of asepsis, ten to fifteen minutes being the average time that the abdominal cavity is open.

In the business part of the city, the first floor occupied by shops, I found Mackenrodt operating on the second floor, his private hospital consisting of the three upper "etagen." He says: "Have only one operating-room, and that always aseptic—make it so before every operation of whatsoever kind." In preparing, he washes the hands in hot water and potash soap with a brush, five minutes, and wears a long rubber apron over sterilized underclothes. He then walks to the opposite side of the operating-room, where he has three porcelain vessels in a row—the first containing a soda solution of two per cent., the second pure alcohol, and the third sublimate. To each he gives about two minutes in the order named, soaking and washing the hands. Before commencing at the porcelain vessels, he places a sterile white linen apron over the rubber one, and this apron is replaced with one of clean linen over the rubber apron before each operation.

The patient is given a bath the day before, shaved, scrubbed, and sublimate solution applied by bandage over the field of operation, which bandage is removed before operating and the same solutions are applied, in the same order as on the hands of the operator. The vagina is scrubbed with a long-handled ivory brush, having bristles on two sides.

Landau has a separate room for operators to wash and prepare before going into the operating-room, and his is the only clinic at Berlin in which I saw ether given. In none of the clinics are the hands or arms covered, and the heads almost never.

At Leipsic, Trendelenburg has the University clinic for general surgery, and Zweifel for women, Sänger having a large private hospital. The preparation is usually with soap, ether, and sublimate, in the order named, Zweifel and Sänger using green soap with sand, and the latter alcohol next after soap. Fine silk takes the place of catgut at Berlin. Trendelenburg boils the silk immediately before using, and leaves it in the bowels, muscle, or peritoneum. He says when properly prepared it becomes encysted like iron wire in bone, if not absorbed, and is harmless. Iodoform is freely used. Excepting by Sänger, chloroform is the anæsthetic preferred.

Neat-fitting covers of very thin rubber over index and middle fingers—one for the vagina, the other for the rectum—are much used in Zweifel's clinic, both digits being used simultaneously at examinations. While operating, one cover is often placed over the thumb, the other over the index finger. These are washed and scrubbed on the fingers the same as other fingers with soap and chemicals, and before being removed they are dried with a towel, thoroughly dusted with rice flour, rolled on themselves down to the tip and placed on a dry plate for the next day, one being used a half-dozen or more times.[1]

Zweifel is having a separate operating-room built for laparotomies, believing this to be necessary. Trendelenburg is having the same thing done, but tells me he does so in deference to public opinion and not because he believes in it.

[1] Specimens were handed around for members of the society to examine, with the explanation that they were thinner than those made in America for the same purpose.

At Dresden, Leopold, of the public Frauenklinik, does not shave and scrub the patient the day before operating, maintaining that she would not be surgically cleaner, and further that the element of dread begins sharply with these previous-day preparations. Prolonged dread is a factor which receives further consideration from Leopold; he very seldom does more than one laparotomy the same day, and that early, usually 7 A.M., for the reason that the second patient would suffer from prolonged dread after waking that morning. His aversion to a second laparotomy is further supported by the thought of possible infection from some of the things pertaining to the operation—room, instruments, operators, etc.—which require considerable time to render safely aseptic. He shaves and prepares the patient in the operating-room after the anæsthetic. Like Sänger, he prefers ether to chloroform.

Of the two hundred and fifty beds in the Carola House at Dresden, about half are surgical, including those for women; and Hofrath Credé is the surgeon. Except washing the patient and the hands of the operator, there is no compliance with the requirements of modern asepsis. Cotton wool and gauze are not even sterilized, though used in cleansing and dressing surgical wounds. No iodoform, corrosive sublimate, or formalin is used. In eighteen months more than fifteen hundred operations were performed by the above methods without surgical sepsis; silver alone being relied upon and applied on wound, gauze, and suture. Pyogenic cavities he washes out with sterilized water, blows into them the powder, or packs in silver gauze, then applies either or both over the wound. These wounds remain absolutely free from inflammatory process; there is no eruption around the border, no swelling, no redness, not even tenderness to the touch.

In the laboratory Credé developed the fact that pyogenic germs cannot live near pure, unminted silver. From this metal he made citrate and lactate, and found them still more potent germicides, differing from other chemicals of this class in being harmless to man. Commercially these drugs are styled "itrol" and "actol." Since my return to America, I am advised that in this country these silver preparations are to be had only through a firm dealing exclusively in proprietary goods, and chiefly those of foreign brand. This is most regrettable, as it will probably prevent the most potent and practical antiseptic discovered from coming into general use. It had impressed me as the most important new thing seen by me while abroad.

The University of Prague, founded 1347, is the oldest now in Europe. It has two official languages—Bohemian and German—every chair having two professors, one for each language. The same arrangement obtains at the clinics. In surgery Mydla and Wölfler are at the head, as are Pawlik and Rothorn in gynæcology; the former of each branch being Bohemian.[1] The regulation linen clothes, rubber aprons, and careful cleansing alike of patient and operator observed at German clinics are seen at Prague. The shaving is confined more to the line of the proposed incision. Pawlik has replaced sublimate with lysol in two-per-cent. solution, having himself experienced very unpleasant symptoms on using sublimate three and four times preceding as many operations the same morning.

Wölfler carries asepsis further than any surgeon I have seen in any country. Under a wide dome of glass roof over the entire amphitheatre, he presents a military aspect as the glaring light rests on his long, clean, white buckskin gauntlets, with his dark blue suit; but Wölfler never lectures before his class without being thus clad. He makes all examinations, even of the nose, mouth and throat, with gloved hands. He requires the same of his assistants, and the gloves are changed for each patient, unless used on unbroken skin or mucous membrane, when washing takes the place of new gloves. After using, the buckskin gloves are sterilized and placed in closed glass jars containing pure glycerin with five-per-cent. carbolic acid. Before using, they are put on the hands, and rinsed clean of carbolic acid, when the examination is proceeded with. This for assistants is the same at examinations as at operations. Wölfler himself leaves the left hand in buckskin, but the right hand has precisely the same kind of rubber cover on thumb and index finger as worn by Zweifel, having these two fingers of the glove cut short, through which the rubber-covered digits project. The hand thus clad removes breast, tumors, bones, and does laparotomies; but in all rectal and vaginal examinations he wears rubber gloves, and sometimes in operating through these channels. Here I may mention were the only occasions when I saw rubber gloves used, and by the only surgeon who used them in my presence in Europe. The operator and all assisting wear white linen caps, alike at removing a breast or doing a laparotomy.

After lecturing and before operating, Wölfler removes the clothing and puts on something like a combination suit of white linen, fastened apron fashion around the neck and body; over this he wears a long apron of pure rubber; and lastly, an apron of sterile linen. The sleeveless arms are covered with white stocking legs down to and within the gloves.

Before the gloves are donned, the field of operation is shaved and otherwise prepared the same as the hands of the operator and those assisting:

1. Hands and arms are washed in hot water and soap, three minutes.
2. Nails are scrubbed, two minutes.
3. Hands and arms are washed and scrubbed in ninety-five-per-cent. alcohol, five minutes.
4. They are then placed in sublimate, 1 : 1,000 solution, for three minutes.

His instruments, like those of Mydla and Pawlik, after sterilization lie in solutions of one-half to one per cent. of carbolic acid until used. Iodoform is replaced with a bluish-gray powder, which is dusted into wounds, and also used in gauze. Wölfer tells me it is prepared from bismuth, and he claims for it superiority to iodoform in three important counts—it is more potent, free from danger, and without odor.

At Vienna there is not much before the knife new to this narrative. I have already described the great hospital, wealth of material, etc.[1]

Chrobak, Schauta, Wertheim, Gussenbauer, and Albert, all leaders, follow the usual rules of cleanliness of German surgeons. Chrobak, of thirty years' continuous service within the same building, is alone in requiring aseptic linen over-garments to be worn by all visitors and attendants within the operating-room; also head coverings for those at operations of laparotomies. No gloves are worn at Vienna. Hot water and soap followed with alcohol, usually fifty per cent., and sublimate, 1 : 1,000, is the rule for the patient and the hands of the surgeon. The newer hospitals have separate rooms for operating on septic and aseptic cases. Gussenbauer is lavish in the use of sterile towels over the patient, table, backs of chairs, around the operating-table, or anything on which operating hands might by accident or need be placed. Instruments for the operator are placed in trays lined with sterile towels, moist and steaming hot. Some operators fill these with sterilized water.

Schauta has his cutting-instruments washed in hot water and soda, then sterilized in carbolic acid before placing them in porcelain trays, submerging the instruments in pure alcohol, from which they are handed

[1] *Vide* a paper by the author in the MEDICAL RECORD, March 19, 1898.

[1] *Vide* "The Different Fields of Operative Surgery and Gynæcology in Europe," MEDICAL RECORD, May 14, 1898.

to the surgeon. He tells me sterilizing by heat spoils the edges of cutting-instruments. Iodoform is generally employed at Vienna, and chloroform is in universal use.

Dollinger, Kézmárszky, Tauffer, and Herzel, of Budapest, wash and scrub with the same solutions used at Vienna; Tauffer devoting ten minutes to soap and brush, one-half minute to alcohol, and one minute to sublimate. In vaginal cases the pubic hair is not shaven. In hysterectomies Tauffer does the regulation scrubbing the day before and binds on sublimate cloth, which is removed and the cleansing repeated before operation next morning. For vaginal operations a bath and a sitz bath are given the previous day, and the sitz bath is repeated preceding the operation. The vagina is douched the day before with hot water containing two per cent. carbolic acid. This is repeated before the operation under chloroform, and after the canal has been washed with soap and gauze. The brush is not used in the vagina. Linen garments are provided only for those engaged at the operation. Kézmárszky is chary of iodoform, placing it sparingly on gauze and using as little of this gauze as possible.

Pus pans, trays for instruments, and such wash-bowls as are to be used by the surgeon after the operation is begun, have the inside rinsed with alcohol which is then ignited, the flame being fed for a minute or two by a small amount of alcohol left in the bowl. Dollinger remarks facetiously: "We do this to make the spirits—evil spirits—disappear." This being done immediately before use, the pus pans are too hot to be placed hard against the skin of the patient, the assistant protecting his own hands with towels. Instruments when taken from the sterilizer are placed in these hot trays, dry, as needed by operator.

At Budapest the hospitals are new and so ideal that I find my daily notes on the details of their construction would require more space than this entire paper. They are not the most expensive nor do they excel in elegance, though they are of respectable size and appearance for a town of six hundred thousand people; but in the application with good sense of the best methods known to us in hygienic science for the safety, health, and comfort of patients, these public hospitals in my belief are unequalled in the world. I have in mind isolated places where all women brought to the hospital with temperature above the normal and of doubtful diagnosis are placed until that is decided. If they are septic from abortion or other cause, as soon as fully understood there are separate buildings where they are kept carefully apart from each other and still farther from all other patients. Other points of distinction are ventilation, which in summer is by air screened, washed, and cooled, through wire and sprays of cold water; conduits from the hospital empty into reservoirs to prevent communication with sewers. These and many other excellences I had seen nowhere else. But to confine myself more strictly to the scope of this paper: There are usually four rooms exclusively for the use of the surgeon—one for septic, another for aseptic cases, a third in which to chloroform and prepare the patient, the fourth for sterilizing instruments and surgical accessories.

Tauffer's operating-room for aseptic cases is on the second floor, and non-communicating except by door to the hall. Next to it is a small room, also non-communicating except one door to the hall. It contains a fine bath tub, also a sitz bath. In this room the patient is given bath, scrubbing, chloroform, and everything preparatory for the knife; then is wheeled out through the hall into the operating-room. Between these two rooms there is a circular hole in the wall, glass covered, through which observations are made and directions given for the convenience of the operator, as successive cases are prepared for his hands. If by accident an impure case is operated on, the room is again made pure by washing from four pipes coming perhaps a foot below the ceiling, widening out saucer-shaped at the bottom. These are such distances from the corners and each other, that the spray from them plays over the entire surface of the ceiling and runs down in part over the four walls of the room, leaving the mopping up of the floor the only part requiring manual aid. These pipes are supplied with a tank, in which any chemical desired can be mixed in the water, all heated to any temperature desired. The floor, walls, and ceiling are of glazed tiling or cement, the latter heavily painted.

Professors Angerer and Winckel, of Munich, do shaving, scrubbing of the patient and surgeon, also preparing material for operation, much as observed at Berlin: Angerer, however, being the only general surgeon I have met among the German race who prefers ether to chloroform. Winckel operates on a Martin table, he does not let the legs of the patient hang down at the foot of the table, however, but has them supported on foot-stools.

At Heidelberg, Czerny is the general surgeon, following in German orthodoxy of asepsis all that pertains to preparations, but a brilliant leader at operations themselves—the latter are outside the limits of this paper.

Kehrer has the Universität Frauenklinik. He is most scrupulous in shaving and cleansing after the more usual strict process already described, using additionally a fine quality of cognac for rinsing the teeth, mouth, and throat, requiring the same of those immediately assisting at laparotomies. Kehrer places great stress on the importance of thus disinfecting the mouth and throat, and is certain that cognac is best for this purpose; and while he explains with energetic gesture and language that none but an inveterate inebriate would swallow cognac or any stimulant before commencing a grave surgical operation, I notice the assistants swallow theirs with evident zest.

In major cases he desires that the patient be in her ward five days, and insists that she be there three days before operation; deeming it important that she become acquainted with her nurses, doctors, and general surroundings, thus reducing the element of fear—of great value in these cases. He washes out the colon, and gives bath and sitz bath daily for several days before operation, but abstains from giving a cathartic on the previous day.

Between the clinics of Paris and those we have seen among the Germans there are great contrasts. In German clinics I had generally perspired without my coat, while in the French clinics I was often uncomfortably cold wearing an overcoat. French surgeons tell me they do not like a temperature below 18° C., but I was present at laparotomies when the thermometer registered 14.5° C. In German operating-rooms placards on the wall forbid conversation, while the brow and scowl of the professor are more forbidding than the placards; the French surgeon usually enters the place of operation with buoyancy and wit, and delights in evoking laughter by his chat. He manifests distress when not surrounded with the same cheery atmosphere. He smokes his cigarette while assistants are preparing the patient, and each time "between acts" is thus resting, chatting, and smoking, while patients are brought in, anæsthetized, shaved, and scrubbed. The surgeon smokes over the operating-table and patient, merely laying aside his cigarette a moment before taking the knife, but always scrubbing the finger tips after putting away the cigarette.

In the German clinics, when special courses are given, placards tell in the strongest language that finger nails and all projecting roots of nails or skin must be clipped absolutely short; the French surgeon, and

more especially his assistants, cultivate long finger nails as an ornament. In German clinics, before the incision in plastic operations in the vaginal tract, a piece of rubber is sewed to the skin of the nates below the field of operation, but covering the anal orifice apron-fashion; or, instead, a bit of cotton wool on a string, lubricated with vaseline, is passed into the rectum to prevent impurity from that source. In Paris all this is disregarded, but the perineum is fully shaven alike for abdominal and vaginal operations, and after the proposed line of incision is shaved this is cleansed the same as are the hands of the operator, which is more elaborate than with the German. After the long finger nails are scraped with a piece of steel, brush and soap are used for a long time with hot water; second, pure alcohol; third, potassium permanganate solution, 1 : 100; fourth, sodium bisulphate saturated solution—this removes the stain of permanganate; fifth, corrosive sublimate, 1 : 1,000.

At vaginal hysterectomy or any operation through that tract, Segond is easily the most clever I have seen in any city of any country. He begins with a hot douche, using a thick nozzle of glass, introducing next a large oval cake of soap, which is so manipulated with hand and gauze as thoroughly to distend and cleanse the canal for operation, no brush being used. Alcohol is burned in trays just as at Budapest. Iodoform is freely used. Segond prefers ether to chloroform, except in cases of diseased lungs or in the aged.

Richelot scrubs and cleanses the same as Segond, but uses a brush in the vagina. In the uterine canal, after washing with douche, he uses pure glycerin containing thirty-per-cent. creosote before and after scraping or cutting. Chloroform is the anæsthetic.

Pozzi also uses chloroform, but no brush for the vaginal canal.

In none of the Paris clinics did I see any covering over the fingers, hands, arms, or heads, and heads often came together over an open abdomen. At one laparotomy I counted five sweat drops as they fell into the abdominal cavity. There was no untoward sequel, and that hospital had no worse record than others as to sepsis.

At Brussels, Jacobs has one operating-room of great length, with an operating-table at each end—one for abdominal, the other for vaginal operations. Both are entirely of brass, and each is surrounded with brass railing. Well back from the foot of the table, for vaginal work, are perpendicular supports on either side, adjustable to any desired lengths, which hold the legs up and quite out of the way of the operator without the aid of assistants, a device first suggested by Sänger. The top of the table consists of two long plates moulded to fit the back and hips comfortably, and so elevated that antiseptic fluids may distend and keep the vaginal tract filled. The opening between the plates in the middle of the table permits débris from the operation to pass down over a glass plate into a large brass bucket.

The room has abundant light; the ceiling, walls, and floor being finished with cement and glazed tiling, painted and polished in spotless white.

There are only two assistants. One gives chloroform, the other threads needles and hands instruments. All wear white cloth gaiters with rubber soles, and a suit of white underwear, and a low-necked apron, leaving the breast and arms bare.

Though French and Flemish are the languages and habits of Brussels, Jacobs is a native of Germany, also educated there, and has his finger nails cut absolutely short. He uses no iodoform, carbolic acid, or corrosive sublimate at all. The patient is chloroformed and shaved in the operating-room, then scrubbed the same as the hands of the surgeon: first, green soap and hot water; second, saturated solution equal parts biborate of sodium and carbonate of ammonium; third, alcohol; fourth, formalin solution, 1 : 1,000 to 1 : 2,000; fifth, ether.

The vaginal canal is cleansed by using, first, a saturated alcoholic solution of green soap applied with sterilized cotton; second, a saturated solution of equal parts of borax and ammonia solution as above, is freely poured into the vagina, dissolving the soap as well as any oily secretion the canal may contain; third, alcohol; fourth, formalin solution the same as above.

For laparotomies, shaving does not extend below the pubic bone, but the washing includes the perineum, over which moist, close-fitting, sterilized cloths are then placed, others over the pubes and thighs, and a sterile towel above the umbilicus. Over these a sheet, from sternum to knees, is placed, with an oval opening a few inches wide and perhaps a foot long, through which the section is made. Ligatures are silk, and sutures silkworm gut; both are boiled in glycerin, which requires a higher temperature than water to boil. Since doing this, he has had no more fistula, though both ligature and suture are left in the abdominal cavity, also buried under mucous membrane or skin. He uses the iron-dyed silk made in Philadelphia, U. S. A. Like Segond, he burns alcohol in vessels used at operations.

At London my observations were confined to the St. Thomas,[1] St. Bartholomew, Samaritan, London, King's, and Guy's hospitals.

Operating-rooms here are yet colder than at Paris, and some of them with open grates burning soft coal fill the operating-room with suffocating smoke and no perceptible heat. Floors of wide boards and soft wood with dirt-filled joints, and picture frames everywhere on the walls containing biblical mottoes, are further adornments of some of the best-known operating-rooms. On cool mornings it was interesting to watch steam rise from the hands of the operator as he turned from the wash-bowl, and the next moment the same emanation from his incision, and again from neoplasms as they were placed about in vessels.

Ether or the A. C. E. mixture is the accepted anæsthetic. Old wooden operating-tables are the rule; the Trendelenburg position is not believed in. Finger nails are worn long, and less pains taken to clean them than at Paris. The surgeon generally removes his coat, often his vest, and sometimes even his shirt before putting on an apron. But asepsis as practised on the continent is practically disregarded at London.

Since my first observation of illustrious surgeons while sitting on hard benches of dingy amphitheatres in Philadelphia, twenty-six years ago, under the spell of the great master of didactics, the elder Gross, whose tongue and pen were the most lucid known in our language; then dozing while Joseph Pancoast lectured, the latter's tongue being as lubberly as the former's knife—but Pancoast wielded a scalpel with the deftest hand I have yet seen—the lesson was still the same in my further studies and observations at Cincinnati and other cities of the West, South, and East, viz.: Great authors and teachers are not the most clever at the knife, and, conversely, the most dexterous surgeon seldom writes, and he is singularly void of charm in diction, whether in the arena of speech or author. To measures his value or profit thereby, we must go to him and observe his work, or learn how and what he does from our better-travelled neighbor.

2621 Fourteenth Street, N. W., May 2, 1899.

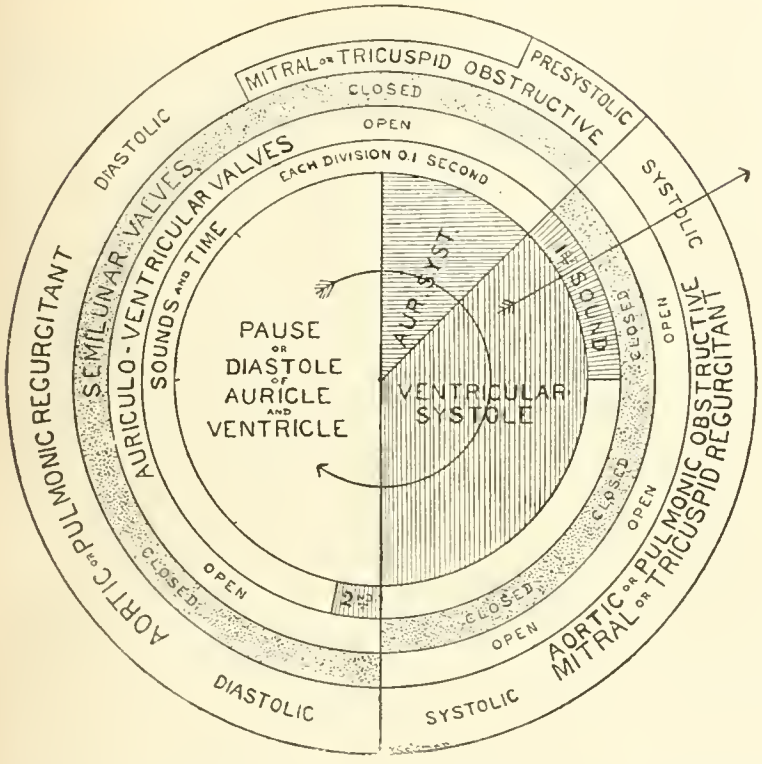
## THE RELATIONS OF CARDIAC MURMURS TO THE EVENTS OF THE NORMAL CARDIAC CYCLE.

By WARREN COLEMAN, M.D.,

INSTRUCTOR IN CLINICAL MEDICINE AND MATERIA MEDICA IN CORNELL UNIVERSITY.

The difficulty often encountered in determining the time-relations of cardiac murmurs has induced me to publish the accompanying diagram. It is an amplification of the older diagram of Sharpey and Gairdner, and includes not only the events of the normal cardiac cycle but their association with murmurs. It consists of a series of concentric circles, representing in order from within outward the chambers of the heart, sounds and time, valves, and murmurs.

The duration of the different phases is based on Foster's computation: thus, the duration of the auricular systole is 0.1 second; of the ventricular systole, 0.3 second; and the pause of the whole heart, during



which neither auricle nor ventricle is contracting, 0.4 second; the entire cycle occupying, at the normal rate of heart-beat, 0.8 second.

The first sound is represented as occurring during the first part of the ventricular systole, as occupying 0.1 second, and with an interval of 0.2 second between it and the second sound. The second sound is heard at the close of the ventricular systole, and is of shorter duration than shown in the diagram.

The valves are represented as open and closed. The murmurs are divided into presystolic, systolic, and diastolic, and are given the usual names.

By following the direction of the curved arrow the proper sequence of all normal and pathological events may be found. By starting at the centre of the diagram and reading peripherally, one will find the normal and pathological events which occur synchronously at any period of the cycle.

The diagram has been constructed chiefly with regard to simplicity, that it may be used for clinical and didactic purposes generally.

**Grand Duke George of Russia,** brother of the Tsar and heir apparent to the throne, has died of tuberculosis.

## TREATMENT OF A SUPPOSED "KISSING-BUG" WOUND, FOLLOWED BY PROMPT RECOVERY.

By F. A. BURRALL, M.D.,

NEW YORK.

A MIDDLE-AGED gentleman called at my office on the evening of July 6th, to ask treatment for an eruption which had appeared on his left forearm. I found on examination that near the capitulum ulnæ was an elevation of about the diameter of a silver three-cent piece, resembling in shape a small nasturtium. On this were four distinct longitudinal vesicles, the longest about the eighth of an inch in length. The wrist and back of the hand were swollen, and flexion and extension of the fingers were accompanied with pain and stiffness. A diffused red, erysipelatoid eruption extended from the wound to the bend of the elbow, covering nearly half the circumference of the forearm, at its upper part. There was no pain on pressure in the axilla. The patient did not complain of great pain nor was there much constitutional disturbance.

On the day before my patient said he had been driving on Long Island, and had been bitten by an insect which he had supposed to be a "kissing-bug," although he had not seen it. He had done nothing for the bite, thinking it would heal spontaneously.

My treatment consisted in painting the inflamed area with the tincture of iodine and directing the patient to take a one-tenth-grain tablet of the sulphide of calcium every two hours. He was also directed to apply carbolic-acid ointment upon the parts and cover this with a linen cloth.

This treatment was followed by rapid improvement. The next day the eruption had retreated to within two inches of the wrist, and now the fingers move freely and painlessly, and the eruption has almost entirely disappeared. The patient called but once at my office, but I followed the case, as I was interested in its course. The tincture of iodine was applied only once.

---

**The Nervous System in Gonorrhœa.**—Dr. Leleneff (*Vratch*, No. 4) states that the following changes have been observed: (1) Changes in the sensory nerves causing anæsthesia, hyperæsthesia, paræsthesia, and pains in the nerves, in the skin, in joints, in muscles, and in internal organs; (2) changes in the vasomotor nerves causing hyperæmia, anæmia, paralysis of vessels, and dermographism; (3) changes in the secretory nerves causing increased or diminished sweating, local sweating, an increase in the flow of mucus from the urethra, etc.; (4) changes in the trophic nerves causing some forms of skin disease, atrophy of the testicle, and muscular atrophy; (5) changes in the motor nerves, causing paresis, paralyses, and twitchings; (6) changes in the skin reflexes and tendon reflexes. Gonorrhœal affections of the central nervous system give rise to a variety of symptoms, such as asthenic neuropsychosis, neurasthenia, hemiplegic phenomena, etc.

## Progress of Medical Science.

**To Render the Hands Aseptic** for operative purposes Paul (*Philadelphia Medical Journal*, May 13, 1899) recommends washing them with a mixture of fifteen parts of acetanilid and one hundred of pure ground castile soap. The same method may be applied to ulcers and superficial wounds.

**The Cancer Parasite.**—Dr. Curtis, of Lille (*La Presse Médicale*, 1899, No. 20), reports totally negative results in his search for a cancer parasite. His deductions are drawn from a series of experiments now in progress for over four years. He calls particular attention to the fact that tissues derived from superficial epitheliomata are not the best to use in experimental work, since they are so liable to be contaminated with various outside organisms. He used carcinomata of the breast and testicle. In a carefully conducted series of experiments with eighteen of such cases, he was unable to obtain any parasites that would grow on any media, and was unable to produce any contagion in other animals. The author believes that the positive results obtained by other observers are due to defective technique.

**Multiple Primary Carcinoma.**—Dr. Aldred Scott Warthin, in *The Journal of the American Medical Association*, May 6th, says: The known cases of multiple carcinoma emphasize the relations between carcinoma and chronic inflammation of epithelial surfaces, and are not explained by the theories of Cohnheim or Ribbert, but lead to a wider application of Thiersch's theory of local predisposition. It does not necessarily follow that multiple primary carcinoma arising in some individual should have no connection with each other, if the cause of the new growth could be shown to be a living parasite. Unfortunately, we are not yet in a position to give positive proof of this, and the study of the cases of multiple carcinoma does not give us any furtherance in this direction. Our present knowledge concerning the etiology of multiple primary carcinoma may be expressed as a theory of multiple seats of a cell anomaly consisting in removal of the normal inhibition of the cell leading to atypic overgrowth, and that in any production of this cell anomaly parasitic, physical, or chemical irritants may play the rôle of a primary exciting factor. Finally, the missing link in our knowledge, be it a parasite or an inherent quality of the cell itself, is yet to be discovered.

**Pancreatic Cysts.**—Kussow (*Deutsche Medizinal-Zeitung*, May 1st) states that cysts of the pancreas are relatively rare. Oser has collected from the entire medical literature one hundred and thirty-four cases. According to their origin we distinguish retention cysts, proliferating cysts, and apoplectic cysts. Cysts which arise through plugging of the pancreatic duct in its passage through the intestines cause a longitudinal dilatation of the duct and form the so-called pancreatic ranula; inflammatory cysts are small and occur secondarily in the smaller ducts. The most frequent size of the cysts is that of an orange; pancreatic cysts the size of a child's head and even still larger are, however, occasionally observed. The walls of these cysts are composed of thick connective tissue, 3–4 mm. thick, and have but few cells; the inner wall is smooth and lacks epithelium. The localization is more frequent at the tail than at the head. The amount of fluid contained within these cysts varies; occasionally it reaches twenty quarts. The contents are rarely clear and transparent, being for the most part cloudy, mucoid, or gelatinous; the color is generally brown. The reaction is alkaline; specific gravity, 1.007 to 1.020. A pancreatic cyst is most frequently due to retention of the pancreatic secretion; this retention is due to: (1) chronic indurative inflammation; (2) stones, catarrh of the ducts, compression of the ducts by tumors of the surrounding organs; (3) trauma. The symptoms consist of vague signs of a gastro-intestinal disturbance, transient or constant headache, dyspepsia, vomiting, occasionally hæmatemesis, diarrhœa or constipation, dejecta which contain considerable fat, undigested proteid in the fæces, glycosuria, albuminuria, and emaciation. Traumatic cysts develop rapidly, those of an inflammatory nature very slowly. Pancreatic cysts occasionally shrink in size; sometimes they open into the bowel. The treatment is surgical. Of the one hundred and thirty-four cases collected by Oser, one hundred and one were subjected to operation, with eighty-one successful results.

**The Causes of Bronchitis.**—In this year's Lumleian lectures, delivered by Dr. Samuel Gee at the Royal College of Physicians in London, the following closing remarks were made: "We have found it to be highly probable that most catarrhs are due to a specific infection, and they often depend upon contagion spreading from man to man. This doctrine has very important bearings upon medical practice. It leads us to believe that the means by which we may prevent catarrh are to be found in ventilation and cleanliness, if, indeed, ventilation be not a kind of cleanliness. Experience confirms this belief. When epidemic catarrh prevails, where do we find most of our patients? In those houses which are obviously the worst ventilated, even though they be the spacious houses of the rich. And where do our patients catch their catarrh? Either in houses of the kind which I have mentioned or in buildings where men most do congregate, especially in offices, shops, and churches. Large shops and stores, public museums and libraries, are ventilated as little as possible for fear of their contents being spoilt by smoke and dust. Many churches both in town and country are never properly aired for another reason—namely, because their architecture does not admit of it. Those 'rich windows which exclude the light' do worse than this—they exclude fresh air. The revival of Gothic architecture has been, from the sanitary point of view, a great mistake. Our despised forefathers of the eighteenth century erected plain and simple buildings which could at least be well aired, well lighted, and kept warm and comfortable; nay, even the much-ridiculed churchwarden, with his brush and pail of whitewash, was a praiseworthy minister of health. Modern dwellings are no better than the churches. In the matter of domestic sanitation people have fixed their attention too exclusively upon the drainage and the water supply; light and air are not reckoned. Many of the large red-brick houses which have been built in great numbers at the West End of London and elsewhere during the last twenty-five years cannot be properly ventilated. The well of the staircase ought in every house to be a reservoir of pure air, and to have an independent supply from without. But in many houses the staircase cannot be ventilated except through the rooms, and, in fact, it never is ventilated. Nor are the rooms themselves much better off: their heavily mullioned windows are designed with small regard to the transmission of light and air. The subsidiary and merely ornamental arts, which do no more than please the eye, are studied to the neglect of that far greater art which promotes the happiness and welfare of the whole man—the art of preserving health."

MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, July 15, 1899.

## THE WATER SUPPLY FROM RIVERS.

THE city of Providence, R. I., is at present discussing the important subject of an improved water supply from a standpoint which must necessarily appeal to all municipalities having like needs. As is proper under the circumstances mentioned, the physicians of the locality are actively interested in the project, and are determined if possible to secure good water at any price.

It would appear that there are many difficulties in bringing the matter to a practical consummation, but these latter, applying as they do to thousands of small cities obtaining their supplies from contiguous rivers, have such a practical bearing upon the general question that they can be discussed on a broader basis than would otherwise be warrantable.

Providence, like other prosperous localities, has thriven and expanded itself. The present water supply, which is mostly from the Pawtuxet River, is insufficient and more or less contaminated by mills and surface drainage up-stream. One proposition is to increase and purify the present supply by sand filtration alone or by the addition of alum, and another to tap the river at its source above the mills and control the watershed by purchase.

There is no question that the latter plan is the best as insuring absolute purity for all time, but the objections appear to be the great expense of the plant and the large outlay for damages to the mill owners whose water power would be curtailed. This, however, is of small moment considering the great good to be accomplished in the end.

Dr. F. H. Peckham, Jr., a leading physician of Providence, voicing the opinion of his professional brethren, takes becomingly strong ground on this point:

"A supply of pure water if obtainable for a municipality is cheap at any price. Other cities take measures to obtain it. In the near future it will be more costly than now, and the present supply will become more polluted, and we may have the experience which Philadelphia is now having in defending itself against suits for damages from typhoid fever directly traceable to the impure water supply."

It is difficult to understand, if filtration is adopted as a compromise, why anything more than the use of sand for the purpose is necessary. Everything that filtration can accomplish can be done by such means. Alum, aside from theoretical assumptions, is not only useless, but may be harmful. We heartily indorse what Dr. Peckham says on this point:

"I have no doubt by the use of the alum process of filtration in the laboratory and on a small scale, supervised by skilled workmen, all the alum can be removed, but the process is no more effectual in removing disease germs than sand or natural filtration, and it is said to be the rule in the use of alum 'to be sure and use enough.' There will always be the suspicion among its consumers, if it is used, that some of the chemical may exist in the water and produce a deleterious effect, imaginary if not real. It is but a few years ago that the newspapers were full of the dangers of using baking-powders containing alum, and medical men are unanimous in the opinion that the use of this chemical is injurious to the human system. Wisconsin and Minnesota have passed laws that all baking-powders containing alum shall have the fact conspicuously printed on the wrappers to warn the consumer of their true character. In the District of Columbia the authorities had, under the direction of Congress, adopted regulations to prohibit the use of alum in bread altogether. By the use of chemicals our water might become so changed as to unfit it for use in many industrial branches."

Looking at the subject in its broad aspect, there is no doubt that the whole question of water supply for our cities needs thorough supervision in view of the new theories regarding disease propagation. The old idea that water purifies itself after flowing a certain number of miles may be tenable enough as regards readily oxidizable products and easily deposited débris, but it is by no means the case with pathogenic bacteria, which can be transported unchanged for very long distances. The conclusion of the whole matter would then appear to be that the only guarantee for safety rests in the absolute title for a perfectly clean watershed beyond all possible chances of pollution.

## THE TREATMENT OF LEPROSY.

DR. ISADORE DYER was recently requested by the Orleans Parish (La.) Medical Society (June 9th), to review the subject of snake venom in the treatment of diseases, particularly its use in cases of leprosy. Snake venom, he said, has been used in the treatment of many diseases in an attenuated and dried form for one hundred years. It was supposed at one time to be most efficacious in yellow fever. About March, 1892, a Jamaica physician reported an instance of unusually rapid recovery of a case of leprosy in a man bitten by a viper. The case, one of tubercular leprosy, was cured in six weeks. The idea occurred to Dr. Dyer to procure an attenuated form of serum and try it systematically in leprosy cases. After a study of the results of Fraser, Calmette, and others, who were preparing serums to be used in cases of snake bite, some of Calmette's antivenene was procured and treatment was commenced in five cases. One to three cubic

centimetres was the daily dose and this was continued for three months. The results, which were reported in detail in the New Orleans *Medical and Surgical Journal* for October, 1897, were striking. Of the five original cases, one, a policeman, who had marked trophic changes, is now (eighteen months later) without evidence of the disease and is working steadily. A carpenter, who was hardly able to dress himself owing to contractures of his hands, is at work and presents only a slight bluish scar; two fingers have remained stiff owing to the nerve having been destroyed. In three other cases, all of atrophic type, the lesions quickly disappeared and no new developments have occurred.

The serum was given subcutaneously and dermatically, the dose varying from 1 to 11 c.c. The injections were made every second day at first; subsequently every day. For the most part they were made in the gluteal regions. Wherever local injections were made into individual lesions the lesions disappeared. Sloughs sometimes occurred, but healthy scars invariably resulted.

Dr. Dyer said that he is now using chlorate of potassium with gratifying results, and he makes it the basis of all treatment. The initial dose is gr. x. daily, which is increased to gr. cxx. or ccc. The latter dose is very seldom required. No serious effects have resulted from the large doses. A systematic treatment in this way of leprosy cases under hygienic conditions will result in a large percentage of cures. This can be arrived at only in special institutions, but the results would certainly justify any outlay in the direction.

## INSURANCE HOSPITALS IN GERMANY.

Germany has taken the initiative in introducing hospitals of a somewhat novel nature. These establishments, which are said to be becoming popular, are erected by insurance companies for the benefit of their sick clients. At the time of the war with Spain, the suggestion was made from many quarters that similar institutions should be founded, so that wounded policy holders might be attended by the physicians connected with the insurance companies rather than by the regular army surgeons. The difficulties in the way of bringing this plan into effect were thought at Washington to be insurmountable, and the idea was abandoned. In Germany, however, hospitals established on these lines have been in working order for some time, and now it has been resolved that special institutions for the care of consumptives should be erected. The *London Insurance*, referring to this determination on the part of life companies, and quoting from the report of the central committee for the erection of consumptive hospitals held some time ago in Berlin, says that: "Three more societies for the establishment of hospitals are being formed, and that eight societies, including the Berlin People's Hospitals Society of the Red Cross, have institutions of their own. Ten societies, including the Berlin and Brandenburg Hospital Society, will establish similar hospitals during the year, and twelve are collecting money for the purpose. Twenty hospitals, including some private ones, take in consumptive patients at low rates. By far the greater number of the beds are intended for men, and the lack of accommodation for women is increasingly felt. It is, however, satisfactory that contributions for free beds are coming in rapidly, especially from the insurance companies, for the sick and aged, which already have three hospitals of their own and are building three more. The largest will be the property of the Berlin Insurance Company. Those companies that have not yet started hospitals of their own support the efforts of others by loans at reduced interests, and the large employers, as well as municipalities everywhere, are co-operating in the effort to combat consumption methodically."

## IMPORTANT DECISION IN REGARD TO THE PRACTICE OF DENTISTRY.

The Supreme Court has recently made a decision in reference to the registration of dentists in Rhode Island which closely affects the medical profession. A physician of Newport was indicted for contravening the law in that he practised dentistry without having first obtained a certificate from the board of registration in dentistry, and without first having caused his name and place of business to be registered with the board. The defence was that at the time mentioned he was qualified to practise medicine and surgery by reason of the possession of a diploma from a reputable and legally chartered college, indorsed by the board of health, and therefore he had the right to practise medicine and surgery in all its branches upon all parts of the human body, including the teeth. Judge Tillinghast upheld this evidence, and in his opinion handed in to the Supreme Court ends with the following words: "It has always been the custom in this State, and probably everywhere else, for physicians to treat ailing teeth, to extract teeth, and to perform various other professional services which technically come within the purview of dentistry. Physicians who reside in the country towns especially have always been called upon to a greater or less extent for the performance of such services, and to now prohibit them from thus treating their patients would be a source of great inconvenience and in many cases of extreme hardship and suffering to the latter, as well as an interference with the proper and legitimate functions of the former."

**Gifts to Hospitals.**—Mr. Henry W. Maxwell, president of the board of trustees of the Long Island College Hospital in Brooklyn, has given $10,000 to the institution for the erection of a new front to the building. Mr. Maxwell has made other gifts to the hospital. Mr. Russell Sage has given $50,000 to the Woman's Hospital in the State of New York, for the new building to be added to the group now belonging to the hospital between Park and Lexington avenues and Forty-ninth and Fiftieth streets.

## News of the Week.

**Scurvy in Alaska.**—Some twenty persons are said to have died of scurvy at Wind City, Alaska. Among those who are reported to have died were Dr. J. B. Mason, a physician, and Dr. Martin, a dentist, both of Chicago.

**St. John's Guild.**—The floating-hospital excursions of St. John's Guild were begun last week. Daily trips will be made by the *Helen C. Juilliard* from East River piers, and by the *Emma Abbott* from landings on the North River.

**Poisoned by Water.**—About fifty railroad-tie cutters near Fort Smith, Ark., have been prostrated, it is thought, as a result of poisoning by water. The men affected drank from an old well which had not been used in several years, and soon every one in camp was seized with fever. Three deaths occurred before medical assistance reached the camp.

**A Suit to Recover Medical Charges.**—A physician in a village of this State has brought suit against a patient for $10,000. The physician made ten visits to the defendant's home during a recent illness of the latter, charging him $1,000 per visit. The defendant has refused to pay, on the ground that the charges are exorbitant. It is not stated in the published report what was the nature of the medical services rendered.

**Smallpox** is said by officials of the Indiana State board of health to prevail more or less all over the State, breaking out continually at most unexpected places. It is feared that an extensive epidemic will appear next winter unless the people can be persuaded to submit to general vaccination. The antivaccinationists are particularly rampant in Indiana, and the present alarming condition is due in large measure to their misleading teachings.

**Yellow Fever in the Harbor.**—A transport arrived from Santiago last week having several cases of yellow fever on board. The vessel and passengers were detained at quarantine, the sick being sent to the hospital on Swinburne Island. In one of the cases, that of Mr. Oscar F. Lackey, a civil engineer of Baltimore, injections were made of the yellow-fever antitoxin, described in a recent issue of the MEDICAL RECORD. The patient was in the third day of his illness when the orrhotherapy was begun, and three injections of the serum were given. At the present writing he is reported convalescent.

**Yellow Fever** continues at Santiago, though the number of cases is growing smaller. Up to July 11th, there had been 142 cases with 29 deaths, of which 122 cases with 24 deaths were among the United States troops. General Wood arrived in the city on Monday of this week, and at once instituted measures looking to the suppression of the epidemic. Two cases were recently reported at Havana, but in one of them the disease was later proven to be typhoid fever. At Vera Cruz, Mexico, the disease still prevails, but the epidemic on the Isthmus is decreasing. On last Saturday there were but eight cases at Panama and none at Colon. The Bishop of Panama died of yellow fever on Sunday.

**Quarantine of a Hospital.**—The Willard State Hospital, situated at Willard, N. Y., is quarantined as a result of an epidemic of diphtheria, with which both patients and employees alike are afflicted.

**The "Kissing Bug"** is causing more or less distress to sundry inhabitants of this city and its environs. The insect does not always kiss its victim, but bestows its favors indifferently on any exposed part of the body. The resultant symptoms are those of acute phlegmon.

**Dr. Mazzoni,** who recently performed a slight operation on the Pope, has been appointed consulting surgeon to His Holiness. The Pope has also given him a full-length portrait accompanied by an autograph dedication.

**A Cemetery Restaurant.**—There is a difference of opinion between the owners of a cemetery near Coney Island and the board of health as to the propriety of having a restaurant within the walls of the graveyard. The health board asserts that an eating-house in such a place is unsanitary, but the proprietors of the graveyard claim that the cemetery belongs to them, and they can let people eat and drink in it if they please.

**A Model Tenement on a New Plan.**—A tenement house, constructed after the plan of Professor Fairchild, of Hartford, Conn., is to be erected in this city. The building will be a fireproof structure eleven stories high and covering an entire block. This house will have a single entrance leading to a court, whence separate entrances will lead to the several elevators. In the basement of the house will be baths, laundry, heating and lighting apparatus, and a cold-storage plant, this last to cool refrigerators in each flat.

**The Plague** still prevails at Alexandria. Three cases were reported there on July 9th, and the usual trouble has followed upon the attempted enforcement of sanitary regulations, two physicians having been set upon and roughly handled by infuriated natives. A serious outbreak is reported at Mauritius, where during the first week in July there were thirty cases of the plague and twenty-four deaths. According to advices received at the State Department at Washington, from the United States legation at Monrovia, Liberia, a disease somewhat similar to the bubonic plague is raging at Grand Bassam, French Ivory Coast Colony. Between two hundred and three hundred persons, including three European physicians, have fallen victims. This colony adjoins the British Gold Colony on the west, and Liberia on the east.

**Another Cancer Theory.**—According to a dispatch in *The Sun*, "Dr. Lambert Lack, a London surgeon, after long investigations, has established the theory that cancer is not attributable to a germ, but is always due to a specific injury to the basement membrane of the mucous membranes and allied structures. Dr. Lack produced cancer in animals by inflicting such

injury. A select committee of the Pathological Society which examined the results of Dr. Lack's investigations declares that they are practically conclusive." Dr. Harry Lambert Lack entered the profession of medicine in 1890 and was formerly resident surgeon of the Hospital for Diseases of the Throat, in Golden Square. Just what his theory of cancer production is, or in what respect it differs from the ordinary theory of traumatism, it is difficult to say from the above description. The question of the treatment of cancer was brought up a few days ago in the House of Commons, and Mr. Broderick, parliamentary foreign secretary, promised to ask the British embassy at Washington to procure the reports of the Buffalo laboratory on the study of cancer in that institution.

**Tapeworm in a Fish.**—Dr. H. E. Douglass, of Independence, Iowa, reports the finding of a tapeworm, measuring twenty-seven feet in length, in the intestines of a pike.

**Italian Medical Society of the City of New York.**—An association with this title was incorporated in Albany in May. The incorporators were Drs. A. Casella, A. Pisani, M. Luzzatto, J. Aquaro, and J. B. Corziglia. Dr. John Aquaro is the secretary of the newly incorporated society.

**Assassination of a Roman Physician.**—Dr. Enrico Bondi, chief of the medical clinic at the Santo Spirito Hospital, was stabbed by a discharged patient on June 13th. The instrument, a sharpened nail, penetrated the large vessels of the neck, and the victim died in about an hour after the assault. Dr. Bondi was forty-two years of age.

**Gift to a Hospital.**—Mrs. C. Knaupp, of this city, has given $10,000 to the new German Hospital in Brooklyn, the sum necessary to complete the building so that it can be opened in the early part of August for the reception of patients. The gift was made on condition that the donor should, if the necessity ever arose, be received and treated at the German Hospital free of charge.

**Surgical Instruments Free of Duty.**—A decision was handed down by Judge Colt of the United States circuit court in Boston on July 7th, reversing the decision of the board of appraisers which held that surgical instruments brought to this country by a medical man for his personal use were dutiable. The court holds that the instruments are not dutiable, being "scientific instruments" within the meaning of the law.

**The Tuberculosis Congress.**—The report of Dr. de Schweinitz, the official delegate to the Berlin Tuberculosis Congress, has been made public by the State Department. It says that the papers presented were thorough reviews of the present knowledge of tuberculosis, from both the scientific and the practical standpoint. The special object for which the congress was called, namely, to arouse interest in the erection of sanatoria for poor sufferers from tuberculosis, will be greatly advanced. According to the present German laws, each laborer and each employer of labor is required to pay a small tax, which is used for this purpose. In this way a large fund has been secured, and at the present time there are fifty sanatoria in the German empire in which the poor can be treated. Dr. de Schweinitz thinks that many practical results will follow the work of this congress. Dr. Boyd, of the United States navy, was the other delegate from the United States. The official name of the congress, translated into English, was "The International Congress for the Restriction of Tuberculosis as a Disease of the Masses."

**Professor of the Diseases of Metabolism.**—Dr. Heinrich Stern, of this city, has recently been appointed professor of the diseases of metabolism in the St. Louis College of Physicians and Surgeons.

**The Hague Peace Conference** has gradually drifted into a discussion of the best means for mitigating the horrors of war. As bearing upon this the following proposals in regard to the Red Cross have been introduced: (1) All wounded to be declared neutrals; (2) a decision to be come to on the question whether wounded when taken prisoners should after their recovery be treated as prisoners of war or sent back to their homes; (3) the convention to be applied to naval warfare; (4) the identity of prisoners of war, of the dead and of the wounded, to be established with the greatest care; (5) knowledge of the Geneva Convention to be compulsory on soldiers; (6) a special campaign police to be created whose duty it shall be to seek for and protect the wounded on the battlefield; (7) ambulances to be established at a sufficient distance from the battlefield in order to avoid contagion; (8) Red Cross Societies to be officially recognized; their *personnel* and appurtenances to be declared inviolable. The adoption of these rules would be welcomed by humanitarians, but it would not tend toward peace. The only effective measure of promoting peace is to increase in every way the horror and wretchedness and destructiveness of war, until the nations pause for very fright.

**The New Mount Sinai Hospital.**—Ground has been broken for the new buildings of this hospital at One Hundredth Street and Fifth Avenue, and it is expected that the work of laying the foundations for the new buildings will begin within a few weeks. The buildings will be of limestone and brick, in the Renaissance style. The main buildings are to be five stories high. The main entrance will be on One Hundredth Street, through the Administration Building. On one side of this building will be a pavilion containing the medical wards, and on the other side a similar structure containing the surgical wards. The Administration Building will contain, besides a main hallway and staircase, the executive offices and all the rooms required for the details of administration. This building will also contain accommodations for the physicians and the operating-rooms. The Fifth Avenue front will be devoted entirely to the private hospital. The Dispensary and the Nurses' Home, two separate buildings, will front on

Madison Avenue. The kitchen, laundry, etc., are to be on One Hundred and First Street, and on the extreme northeast end of the block will be the morgue and the contagious-disease wards, both entirely separate from the rest of the system. The roofs of the buildings are to be flat and partly inclosed, so that they may be used as roof gardens in summer and as sun parlors in winter.

**Fire in Bellevue Hospital.**—A small fire occurred Monday night in the infants' pavilion of Bellevue Hospital, starting when the canopy over a bed caught fire from a candle carried by a nurse. The blaze ran from crib to crib, but an ambulance driver and several nurses worked successfully at pulling down the burning netting.

**Scarlet Fever at West Point.**—Nine cases of scarlet fever have occurred at West Point, seven of the cadets and two enlisted men in the band being ill.

**International Antivivisection.** — An antivivisection booth is planned for the Paris Exposition, and several excited individuals purpose to carry on a vigorous campaign against scientific pursuits in Paris. Each of the societies is to send a beautiful banner to adorn the booth, and within these will be a real chamber of horrors, consisting of an exhibit of instruments used in vivisection and also wax figures of animals in the process of being cut up alive. We would suggest an improvement in the way of a phonograph to reproduce the agonized cries of the victims of man's cruelty.

**Diminishing Malaria in Norfolk.**—The city of Norfolk, Va., has been unusually free from malarial poisoning the past spring. Whether this improved condition will continue depends in great part doubtless upon the city's water supply, which is now undergoing many improvements, chief among which is the construction of a filter.

**Northeast Missouri Medical Association.** — The annual meeting of this society was held in Unionville, Mo., July 11, 1899. The following are the officers of the association: *President*, Dr. J. T. Jones, Queen City; *Vice-President*, Dr. W. E. Dicken, Kahoka; *Secretary*, Dr. E. E. Parrish, Memphis; *Treasurer*, Dr. O. F. Pile, Memphis.

**Physical Defects in Would-be Recruits.**—The officials at the naval recruiting office in Norfolk are in somewhat of a quandary regarding applicants for position in the United States navy. Within the past two months something like thirty-five applicants have been examined, but only about one-seventh have been admitted. They do not come up to the physical requirements. Just why this is remains a question. Apparently the men are well developed, but they fall short when they are measured by Uncle Sam's tape.

**The Famine in Russia.**—According to reports from Odessa there promises to be no relief to the famine which has prevailed the past winter in southern Russia. The summer crops in large areas have been so badly damaged by drought that they will not be worth reaping. The reports also state that there will be no hay and very few vegetables. Coming on top of the failure of the winter crops, the situation promises extreme misery for the people. In addition to the distress in this region, the correspondent of the London *Times* at St. Petersburg writes that the condition of the seven provinces of east European Russia is worse than it was during the famine of 1891 and 1892. "Quite half a population of eleven million," he says, "are undergoing terrible suffering, starvation, and disease, and the authorities everywhere appear incapable and unprepared to deal with the calamity. Money is squandered in absurdly high pay to relief agents, and, owing to the high prices which the Government charges for seed corn, no encouragement is given to the peasants to till the ground."

**Another Medical School Threatened.**—It is rumored that a number of Norfolk physicians contemplate the erection of a medical college there. Norfolk being very accessible and a growing city, the projectors believe that a medical school there would prove a paying investment.

**A Small Baby.**—It is reported that the Graz Hospital, in New Haven, Conn., has in its custody a girl baby, a week and a half old, and weighing three pounds. She is about ten inches long. At birth she was put into a hastily improvised incubator, and has been thriving ever since.

**Another Medical Mayor.**—Dr. John C. Fahey was on June 3d elected mayor of Wilmington, Delaware. He is a graduate of Jefferson Medical College in the class of 1883, and has been county physician, coroner's physician, a member of the board of education, and a member of the board of health.

**Harlem Medical Association.**—At the meeting of the Harlem Medical Association, on June 12th, the following officers were elected to serve for the ensuing year: *President*, Dr. Henry W. Mooney; *Vice-President*, Dr. Montrose R. Richard; *Secretary*, Dr. Joseph E. Lumbard; *Treasurer*, Dr. William F. Farrell.

**Drugging Recruits.**—Two physicians were recently arrested in Elberfeld and Remscheid, towns of Rhenish Prussia, on the charge of drugging recruits, who sought thereby to be exempted from military service. Four of the persons thus treated are said to have died from the results of the drugs administered to them.

**International Conference upon Syphilis.**—An international conference to discuss the prophylaxis of syphilis and venereal diseases will be held in Brussels in September. The secretary is Dr. Dubois-Havenith, No. 19 Rue de Gouvernement Provisoire, Brussels.

**How to Keep Mosquitoes Alive.**—A writer in *The British Medical Journal* says that mosquitoes can be kept alive for a long time by feeding them sherry and sugar. If he had told how to exterminate them, his prescription would be more popular.

**The Red Cross in Japan.**—The total number of the members of the Japan Red Cross Society at the end of April last throughout the country was 590,341, of whom 24 were honorary members, 1,851 special members, 572,040 ordinary, and 16,426 associate members.

**Jewish Hospital, Philadelphia.**—Dr. J. C. Knipe has been elected ophthalmic and aural surgeon, and Dr. David Riesman consulting physician.

**Navy Department, Bureau of Medicine and Surgery, Washington, D. C.**—Changes in the medical corps of the United States navy for the week ending July 8, 1899. June 30th.—Assistant Surgeon Ralph W. Plummer appointed assistant surgeon from June 17, 1899. July 3d.—Medical Inspector J. C. Wise granted sick leave for three months.

**A Physician Pleads Guilty of Murder.**—Dr. C. S. Murray, a young physician, on March 12th, shot his negro coachman, at his father's home in Sewickley. Upon being arraigned in court, he pleaded guilty to murder.

**Dr. E. N. Brush,** superintendent of the Sheppard and Enoch Pratt Hospital, has been elected professor of mental diseases at the College of Physicians and Surgeons. Dr. W. F. Lockwood, former member of the Maryland State board of medical examiners, has also been elected to a professorship at the college.

**The Philadelphia Pædiatric Society.**—At a stated meeting, held June 13th, Drs. J. C. Gittings and C. F. Judson presented a communication on "Pheumonia in Children." Dr. L. C. Peter reported a case of rumination in a boy of seven years old, in which good results were secured through suggestion and administration of bromide. Dr. Peter reported also a case of muscular pseudo-hypertrophy in a boy about six years old, who presented enlargement and hardness of the muscles of the calves and of the rhomboid muscles, with general muscular weakness. There was a strong neuropathic family history, but no other case of the same disease in the family. Dr. Albert Woldert reported a case of urticaria pigmentosa in a child aged two years, and exhibited the patient. Dr. Stretch reported a case of scurvy in a child. Dr. T. P. Twaddell reported a case of Henoch's purpura in a child.

**A Memorial to Dr. Stickler.**—It is announced that a public library building will be erected in Orange, N. J., in memory of the late Dr. Joseph W. Stickler.

**Sir Alexander Armstrong,** K.C.B., formerly director-general of the medical department of the British navy, died July 4th. He served five years in the Arctic regions, searching for Sir John Franklin, and was on the *Investigator* when the Northwest Passage was discovered. During the Crimean war he served on the Baltic. He wrote "A Personal Narrative of the Discovery of the Northwest Passage." In 1869, he became director-general of the medical department of the navy, from which office he retired in 1880.

**The Late Dr. Francis E. Noble.**—At a special meeting of the committee on necrology of the District Medical Society of the County of Hudson, held in Jersey City, July 1, 1899, to take action on the death of Francis E. Noble, M.D., the following resolutions were formulated and will be presented at the next meeting of the society:

"*Whereas*, We have learned with deep regret of the death of that worthy man, eminent scholar, and humanitarian physician—Dr. Francis E. Noble; and

"*Whereas*, The District Society of the County of Hudson feels with unalloyed sorrow the loss it will sustain in Dr. Noble's death—

"*Resolved*, That we thus publicly express our appreciation of the man, our admiration for his character, and our individual loss in the death of Dr. Francis E. Noble; and

"*Resolved*, That we tender our condolences to his family and friends, ever reminding them that as the brightness of Dr. Noble's intellect has been always a lamp unto our feet in times past, so shall his memory be as a luminous star beckoning us onward toward manliness, truth, and virtue; and

"*Resolved*, That a copy of these resolutions be sent to the bereaved family of Dr. Noble and be printed in the New York medical journals, the New York *Evening Journal*, and the *Evening Journal* of Jersey City, and spread in full upon the minutes of the District Medical Society of the County of Hudson."

Committee: Charles K. Law, M.D., *President;* H. H. Brinkerhoff, Jr., M.D., *Treasurer;* G. W. Shera, M.D., *Secretary.*

**Obituary Notes.**—Dr. William Howard Neilson, of New Rochelle, N. Y., died on July 6th, following an operation for appendicitis. He was born in New Brunswick, N. J., in 1858, and was a graduate of the Bellevue Hospital Medical College in the class of 1891. He was a member of the Westchester County Medical Society and of the New Rochelle Medical Society, and was a Democratic member of the board of aldermen in New Rochelle at the time of his death. His widow and one daughter survive him.—Dr. Robert A. Linendoll, of Fort Edward, N. Y., died suddenly of heart disease July 9th, aged forty years. He was graduated from the Albany Medical College in 1879. He leaves a widow and two daughters.—Dr. James E. Graham, of Toronto, died at Gravenhurst, Ontario, on July 7th. He was graduated from the medical department of Toronto University in 1870, and later served a term as resident physician in the Brooklyn City Hospital. He was ill when the Ontario Medical Association met recently in Toronto, but a resolution of sympathy was passed by the members present and he was unanimously elected to the presidency. He was one of the founders of the association in 1881. He was a member of the American Dermatological Association, and in 1889 was its president.—Dr. Mary Edmonds, of San Francisco, died on July 9th of fright caused by the accidental setting off of a burglar alarm in her house. Mrs. Edmonds was a homœopathic physician, a graduate of the Hahnemann Hospital College of San Francisco in 1885. She was the widow of Judge Edmonds, late of the superior court, and leaves a daughter and two sons, one of the latter a physician.—Dr. James A. Ziegler died suddenly at Philadelphia on July 7th at the age of seventy-two years. He was graduated from Jefferson Medical College in 1849, but after fifteen years' practice of his profession he took up mercantile pursuits

# Reviews and Notices.

TWENTY-SEVENTH ANNUAL REPORT OF THE MANAGERS OF THE MIDDLETOWN STATE HOMŒPATHIC HOSPITAL, AT MIDDLETOWN, N.Y., TO THE STATE COMMISSION IN LUNACY, for the year ending September 30, 1897.

THIS sets forth in an accurate and well-arranged manner the working of the hospital. The volume abounds in excellent illustrations of the various parts and surroundings of the Homœopathic Hospital.

CHEMISTRY: GENERAL, MEDICAL, AND PHARMACEUTICAL, INCLUDING THE CHEMISTRY OF THE UNITED STATES PHARMACOPŒIA. A Manual of the Science of Chemistry, and its Applications in Medicine and Pharmacy. By JOHN ATTFIELD, F.R.S. Sixteenth Edition. Philadelphia and New York: Lea Brothers & Co. 1899.

THIS work has for over thirty years been a classic. We hope that it may be in use thirty more, for as a general manual for students we believe that it has no equal. Most of the general chemistries devised for the medical and pharmaceutical student are miscarriages of this parent, and it must be confessed few of them get beyond mid-term. The present edition has been consistently revised. The changes are not many, but they reflect the gradually changing views that are incident to any growing branch of knowledge. In mechanical get-up the work conforms to its previous good standard.

DIE NEUERE GESCHICHTE DER MEDICIN. Kurz dargestellt von O. v. BOLTENSTERN, in Bremen. Leipsic: C. G. Naumann. 1899.

TO those to whom a certain amount of retrospect is enjoyable, the ideas gained from a good history of medicine are salutary, if not positively inspiring. The present small volume sketches in bold outline the general progress of medicine since the sixteenth century. It also develops the history of the specialties in a popular and readable manner. It is to be thoroughly recommended.

THE MEDICAL COMPLICATIONS, ACCIDENTS, AND SEQUELÆ OF TYPHOID OR ENTERIC FEVER. By HOBART AMORY HARE, M.D., B.Sc., Professor of Therapeutics in the Jefferson Medical College of Philadelphia; with a special chapter on the Mental Disturbances Following Typhoid Fever, by F. X. DERCUM, M.D., Clinical Professor of Diseases of the Nervous System in the Jefferson Medical College. Philadelphia and New York: Lea Brothers & Co. 1899.

RECENT experiences have served to accentuate the need of just such a treatise as Dr. Hare has given to the medical public. In six chapters he discusses the general features of the disease, the variations in the mode of onset, the aberrant symptoms, the states or complications of the developed stage of the disease, the many complications of the period of convalescence, the conditions which ape typhoid fever, and the immunity enjoyed from further attacks and the conditions which affect the duration of this immunity. Dr. Dercum contributes a seventh chapter on the mental complications. It is impossible critically to analyze the many points of excellence in this volume; it should be read to be appreciated at its true value.

MEDICAL AND SURGICAL REPORTS OF THE BOSTON CITY HOSPITAL. Tenth Series. Edited by H. L. BURRELL, M.D., W. T. COUNCILMAN, M.D., and C. F. WITHINGTON, M.D. Boston: Published by the Trustees. 1899.

IT has given pleasure to commend the reports of the Boston City Hospital, because they exemplify a high type of work which unfortunately is rare in this country. This, the tenth series, presents a number of interesting and valuable contributions to medical science. The fifteen studies respectively are: "Scarlatina," by J. H. McCollom; "Scarlet Fever: Its Bacteriology and Gross and Minute Anatomy," by R. M. Pearce; "Observations on the Weight of the 'Normal' Heart in Adults in Two Hundred and Sixteen Cases," by H. D. Arnold; "Bone Tumor in the Human Brain Surrounding Encysted Coccidia Oviformia," by J. J. Thomas; "Two Cases of Infection with the Bacillus Capsulatus Mucosus Friedländer," by L. W. Strong; "Secondary Infection of the Skin and Subcutaneous Tissues by the Bacillus Typhosus," by J. H. Pratt; "Actinomycosis," by D. H. Walker; "The Blood in Diphtheria," by J. L. Morse; "A Review of the Diseases Contracted in the Cuban Campaign of 1898," by H. Jackson; "Coincident Malaria and Typhoid Infections as Seen among our Returned Soldiers," by C. F. Withington; "Observations on Pneumohydrothorax and Pneumothorax," by F. H. Williams; "Syringomyelia; Glioma of the Spinal Cord; Laminectomy," by W. N. Bullard; "Cases of Acute Abdominal Inflammation," by J. C. Munro; "An Apparatus for Maintaining Position in Fractures of Both Bones of the Leg," by R. W. Lovett; "A Case of Cantharides Poisoning, with a Study of the Urine," by R. E. Stevens.

Reports of this style are preferable to the statistical tables doled out by numerous other institutions.

CLINICAL LECTURES ON NEURASTHENIA. By THOMAS D. SAVILL, M.D., Physician to the West End Hospital for Diseases of the Nervous System, London. London: H. J. Glaisher. 1899.

THE author has collected together in book-form lectures delivered as a part of a post-graduate course given at the Welbeck Street Hospital for Diseases of the Nervous System. The several chapters treat of: Pathology of Functional Diseases of the Nervous System; On Nervousness or Neurasthenia; The Diagnosis of Neurasthenia, its Pathology and Relations to Gastric Disorder, and its Treatment; The Mental Symptoms of Neurasthenia and Neurasthenic Insanity, with an Addendum of bibliographic interest.

ALBUMINURIA AND BRIGHT'S DISEASE. By NESTOR TIRARD, M.D., F.R.C.P., Physician to King's College Hospital, and Senior Physician to the Evelina Hospital for Sick Children; Professor of Materia Medica and Therapeutics at King's College. With original illustrations. London: Smith, Elder & Co. 1899.

IN seventeen chapters the following story is told: Structure and Functions of the Kidneys and Tests for Albumin; Albuminuria, Extrarenal and Renal; Hæmaturia; Hæmoglobinuria; Renal Casts; Acute Nephritis; Scarlatinal Nephritis; Chronic Nephritis; Cirrhosis of the Kidney; Puerperal States; Retinal Changes; Lardaceous Disease; Congestion of the Kidney and Renal Embolism; Renal Calculus; Hydronephrosis, Consecutive Cirrhosis, and Suppurative Nephritis; Uræmia; General Diagnosis of Albuminuria; General Prognosis of Albuminuria, etc. In giving this brief outline, the skeleton only of this excellent treatise is laid bare. The work is essentially one for the clinician, and is full of practical suggestions on diagnosis and treatment. It may be considered less thorough from the chemical side, since one finds little discussion of the many proteids which more recent research has found in the urine. While many of these albumin products are still of theoretical interest only, they are daily becoming understood in a practical manner.

RECHERCHES SUR LES MATIÈRES COLORANTES DU FOIE ET DE LA BILE, ET SUR LE FER HÉPATIQUE. Par MM. A. DASTRE, Professeur de physiologie à Paris, et N. FLORESCO, Docteur en sciences. Paris: Steinheil. 1899.

FOR the physiological chemist this is an extremely interesting, small monograph of about two hundred pages. The authors first discuss the general biliary pigments, and then take up the separate isolated products and the bile pigments as found in various animals, including the bile of birds, reptiles, and batrachians; a second part of the study is devoted to the study of the iron compounds of the bile, and the determination of iron in the liver and the tissues of vertebrates and invertebrates; a third part deals with hepatic pigments in all classes of animals in which such coloring matters are found.

LABORATORY WORK IN BACTERIOLOGY. By FREDERICK G. NOVY, Sc.D., M.D., Junior Professor of Hygiene and Physiological Chemistry, University of Michigan. Second edition. Ann Arbor, Mich.: George Wahr. 1899.

THIS is really a very excellent book on the general subject of bacteriology, though meant for a laboratory guide. The different chapters discuss the form and classification of the bacteria, size and structure of the bacterial cell, life history and environment of the bacteria, and their chemistry; the microscope, the hanging drop, and methods of staining; the

different media and methods of cultivation; non-pathogenic bacteria; the relation of bacteria to disease, and the special pathogenic bacteria; yeasts, moulds, and streptotrices; examination of water, soil, and air, and special methods of work. The work is well illustrated, and is to be recommended to laboratory workers.

NEWER REMEDIES, including their Synonyms, Sources, Methods of Preparation, Tests, Solubilities, Incompatibilities, Medicinal Properties and Doses as far as Known, together with sections on Organo-Therapeutic Agents, and Indifferent Compounds of Iron; a Reference Manual for Physicians, Pharmacists and Students. By VIRGIL COBLENTZ, A.M., Phar.M., Ph.D., F.C.S., etc., Professor of Chemistry and Physics in the New York College of Pharmacy; author of "Handbook of Pharmacy"; member of the Chemical Societies of Berlin and London; Fellow of the Society of Chemical Industry, etc. Third edition. Philadelphia: P. Blakiston's Son & Co. 1899.

THIS muslin-bound volume of one hundred and forty-seven pages represents an enlarged and revised edition of a useful work of reference. The print is small; in fact too fine for the good of the reader's eyes, and for the best and most attractive presentation of the writer's valuable material.

TRANSACTIONS OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNÆCOLOGISTS. Vol. XI. Philadelphia: William J. Dornan. 1898.

THIS report of the meeting held in Pittsburg covers three hundred and seventy-two pages, contains a number of illustrations, and is well printed and bound. "The Evolution of Specialism" is the title of President Reed's address. Following this are papers and discussions upon a wide range of subjects connected with the association's work. The many friends of the late Dr. George H. Rohé will doubly prize the volume for the biographical sketch, written by Dr. Potter, and the excellent portrait of this versatile and gifted physician.

NERVOUS AND MENTAL DISEASES. By ARCHIBALD CHURCH, M.D., Professor of Clinical Neurology and of Mental Diseases and Medical Jurisprudence in the Northwestern University Medical School, etc.; and FREDERICK PETERSON, M.D., Clinical Professor of Mental Diseases in the Woman's Medical College, New York. With 305 illustrations. Philadelphia: W. B. Saunders. 1899.

IN these works, for in reality they are separate treatises, we have two model text-books. It is unquestionably a difficult matter to gather together a large number of facts belonging to any field of knowledge, and be able, among the many uncertainties and conflicting views, to put them into such didactic shape that they can be made a foundation for students and yet not do violence to many of the facts. A general philosophical treatment of the subject-matter would take into consideration the many inconsistencies pertaining to the science, but would be unavailing to the student who does not possess enough of the facts to make the philosophical relationships of value. A terse, didactic, *ex cathedra* method, so universally employed by most of our text-book writers, while serving the purpose of examination-passing, gives the student no true insight into the general methods of study, nor does it open up his mind to questions which must be solved. We believe that the present volume presents a just medium between these two extremes. The larger part of the work (six hundred pages) treats of the diseases of the nervous system, and is the work of Dr. Church; the remaining (two hundred pages) is from the pen of Dr. Peterson. In Part I. the following is the outline of the subjects treated: Examination of the Patient; Diseases of the Cerebral Meninges and Cranial Nerves; Diseases of the Brain Proper; Diseases of the Spinal Meninges and the Spinal Nerves; Diseases of the Cord Proper; Diseases of the General Nervous System with Known Anatomical Basis, including Multiple Sclerosis, Syphilis, etc.; Diseases of the General Nervous System without Known Anatomical Basis, including Trophoneuroses, Motor Neuroses, Fatigue Neuroses, Neurasthenia, Hysteria, Epilepsy, etc. The second part of the book, on Mental Diseases, is divided into thirteen chapters. These treat of Definition and Classification of Insanity; General Etiology of Insanity; General Symptomatology of Insanity; Examination of the Patient; General Treatment. Then follow chapters on the special types—Mania; Melancholia; Circular Insanity; Epileptic Insanity; Dementia and its Varieties; Paralytic Dementia; Paranoia; Idiocy.

For the subject-matter of both authors we have unqualified praise. The publisher has done his part in the work, and we believe that the treatise will merit a wide circle of friends.

EXPERIMENTAL STUDY OF CHILDREN, INCLUDING ANTHROPOMRETICAL AND PSYCHO-PHYSICAL MEASUREMENTS OF WASHINGTON SCHOOL CHILDREN; WITH BIBLIOGRAPHY. By ARTHUR MACDONALD. Report of Commissioner of Education. Washington: 1899.

SUCH a large number of careful and complete measurements of school children have not been made for some time, and the author of this report is to be congratulated upon his achievement. From a strictly scientific point of view such statistics are of inestimable value, and it is rare to find an investigator with patience enough to undertake the task. It is one of the fundamental principles of general science that a knowledge of individual factors is necessary for the forming of correct generalizations. In sociological science, in ethics, and in many related domains such careful individual studies have yet to be made. The present study will prove of service to the educator, and we hope the author may continue his work.

TREATISE ON HUMAN PHYSIOLOGY. For the use of Students and Practitioners of Medicine. By HENRY C. CHAPMAN, M.D., Professor of Institutes of Medicine and Medical Jurisprudence in Jefferson Medical College, Philadelphia; Chairman Board of Curators, Academy of Natural Sciences of Philadelphia; Member of the College of Physicians, of the Zoölogical Society, Philadelphia, of the American Philosophical Society, and of the American Physiological Society. Second Edition. Illustrated with 595 engravings. Philadelphia: Lea Brothers & Co. 1899.

WHILE not to be classed with such more pretentious works as those of Schaeffer or Landois and Stirling, the present treatise is well worthy of a place in the foremost ranks of American physiological literature. The author has not made the mistake of allowing his volume to grow to a size making it impossible for the average student to compass it in the time ordinarily allotted to the subject in medical colleges, while at the same time nothing of importance has been omitted. In this second edition the principal changes are to be found in the sections on chemistry and the nervous system, these being the provinces in which the greatest progress has lately been made. Too much cannot be said in praise of the illustrations, which are unusually numerous and excellent, while the whole volume is a fine example of modern book-making.

DIE ZUCKERKRANKHEIT. Von DR. MED. OTTO HEZEL, pract. Arzt in Wiesbaden. Leipzig: Druck und Verlag von C. G. Naumann.

THE author has accomplished in a very commendable way his purpose of presenting to the profession in compact form what is at present known about the etiology, course, and therapy of diabetes. The discussion of the disease itself is preceded by a chapter on the chemistry and physiology of the carbohydrates in general, and by another on the glycosurias of other than diabetic origin. The chapter on symptomatology is classified according to the various systems of the body and the pathology of each described at the same time. In considering the disease from a theoretical standpoint, the author makes numerous forms of the disease in accordance with the varying clinical pictures presented, but from the practical ground of treatment he reduces them all to the three degrees of mild, moderately severe, and severe. The chapter on diagnosis will be found of especial value by the practitioner. All the remote symptoms which indicate the possible existence of the disease are tabulated; the differential diagnosis between ordinary glycosuria and diabetes is given, as are also the symptoms indicating threatened diabetes; and, finally, a very detailed account of the most serviceable reactions for the clinical determination of glucose in the urine. The last chapter is devoted to the treatment, and in the main adheres closely to the tenets of Naunyn and v. Noorden. An appendix gives valuable tables of the percentage composition of food stuffs with their equivalents in calories, and a fairly good bibliography is appended to each section of the book.

# Society Reports.

## AMERICAN SURGICAL ASSOCIATION.

*Twentieth Annual Meeting, Held in Chicago, May 31, June 1 and 2, 1899.*

THE association met in the hall of the Chicago Medical Society, and was called to order by DR. W. W. KEEN, of Philadelphia. PROFESSOR DE LASKIE MILLER, of Chicago, delivered an address of welcome, which was responded to by the president. The first vice-president, Dr. Albert Vander Veer, of Albany, then took the chair, and President Keen delivered his address. He selected for his subject:

**The Technique of Laryngectomy.**—He began by saying that he had been ill satisfied with the usual technique of laryngectomy, and as in a recent case he had adopted a method which rendered the operation one of simplicity, caused but little loss of blood and little shock, and avoided the danger of aspiration pneumonia, he ventured to bring it before the association, in the hope that it would be tested by others so as to determine its real value. Instead of being a very severe and dangerous operation, as it had hitherto been regarded, he hoped this mode of procedure would place it in the category of safe operations. Nearly all authors, whether surgeons or laryngologists, spoke of the operation as an extremely severe and dangerous one, and this view was warranted by its past high mortality. Thus Rutsch speaks of the recovery as "very doubtful." Sendziak states that up to 1881 thirty cases had been operated upon with seventeen deaths, a mortality of 56.7 per cent., and that in all the thirty there was only one definitive cure—that is, in which three years or more had passed without recurrence. Later statistics, fortunately, had proved progressively more favorable. Thus Sendziak tabulated from 1873–1894 188 cases of laryngectomy for carcinoma. The results were thus given: (1) Recurrence, 32.45 per cent.; (2) Relative cure (less than three years), 6.9 per cent.; (3) Definitive cure (three years or more), 5.85 per cent.; (4) Deaths, 44.7 per cent. Schmiegelow had tabulated fifty cases of total laryngectomy from 1890 to 1897, and these still later statistics were far from encouraging. The results were: (1) Recurrence, 20 per cent., a fall of 12 per cent. from Sendziak's table; (2) Relative cure, 48 per cent., a rise of 41 per cent. from Sendziak's table; (3) Definitive cure, 10 per cent., nearly double that of Sendziak's table; (4) Death, 22 per cent., one-half that of Sendziak's table. The mortality, it would be observed, therefore, had been halved and the definitive cures doubled, as compared with Sendziak's statistics. If the cases occurring from 1890 to 1894 were to be excluded from Sendziak's statistics, the relative difference would be even more favorable. The causes of the mortality were chiefly: (*a*) weakness of the patient by reason of the disease, the poor aeration of the blood, and the entrance of septic discharges from the diseased larynx into the lung before the operation; (*b*) shock, including hemorrhage during the operation; (*c*) after the operation, septic pneumonia, due to the aspiration of infected wound fluids. This was the greatest danger of all. The causes of these wound fluids were twofold: first, the tracheotomy wound, if, as was usual, tracheotomy had been done; and, secondly, the wound left by the removal of the larynx. These wound fluids were usually infected from the food, the secretions of the mouth, and the packing by iodoform gauze which rendered primary union impossible. While the method which he wished to describe did not obviate the weakness or any other unfavorable influence from the general condition of the patient prior to operation, it minimized the other causes of death, and especially the possibility of pneumonia. He could not claim originality for any one of the steps, for they had all been employed, he believed, by others. Thus Bardenheuer closed the communication between the trachea and the pharynx, but he kept it closed only until the wound became covered with granulations, and until complications were no longer to be feared, say fourteen days. The communication was then reopened for the insertion of the artificial larynx. After adopting this method he had four recoveries, while by the former method he had had four deaths. Cohen united the stump of the trachea to the skin, one of the most important improvements in the technique, since it prevented in a large measure the access of wound fluids to the lungs. Other surgeons also had used the Trendelenburg posture, etc. But as a systematically planned operation, combining many advantages, the present technique as a *tout ensemble* may be called original.

The general preparation of the patient was the same as for any other operation.

Preliminary disinfection: As in all cases about the mouth, nose, pharynx, and larynx, he was particularly careful to make a systematic attempt for two or three days beforehand, to secure at least partial disinfection. While partial disinfection was not so good as complete, yet the results in treatment of fractures of the base of the skull, in the extirpation of rectal tumors, etc., showed its great value. He had the teeth very carefully cleansed with the toothbrush. If there were any old stumps of teeth present it was better that they should be extracted, and the operation deferred a few days until these dental wounds healed. For two or three days before operation, he had the mouth and each nostril sprayed separately every two hours, when the patient was awake, with a solution of boric acid, listerine, or both.

Tracheotomy: Nearly all authors recommended a tracheotomy either as the first step of the operation or more frequently ten to fourteen days before. In the few cases in which dyspnœa was great he was disposed to do a tracheotomy, say two weeks before the laryngectomy; not, however, with a view of preventing the entrance of blood and wound fluids into the lungs by the introduction of a tampon cannula, but for the purpose of improving the general condition of the patient. In the case which was the basis of this paper he did a tracheotomy at the time of operation, but removed the tracheal tube at the termination of the laryngectomy, immediately closed the wound in the trachea, and obtained absolutely primary union. In any future case he was strongly of opinion that it would be better to omit tracheotomy entirely. As he would show, it was not, in his opinion, needful, and by omitting it one cause of septic pneumonia would be eliminated.

Posture: The entire operation, after the trachea was invaded, was done with the patient in the Trendelenburg position. He was quite persuaded that the majority of surgeons did not appreciate to its full the advantages which this posture possessed in all operations about the upper air passages. As he had pointed out in a previous paper, he employed it in epithelioma of the lip, in extirpation or other operations on the upper and lower jaw, in removal of the tongue, in cleft palate, in operation on the tonsils and pharynx, and all similar operations. Blood would not run up hill any more than water; hence, if this posture was employed in laryngectomy, one of the chief reasons for tracheotomy and the employment of a tampon cannula was avoided.

The disadvantages of tampon cannulæ were very great. Kocher, like himself, had lately dispensed

with them entirely. The three most commonly used were those of Trendelenburg, Hahn, and Gerster. Of the three, Gerster's was distinctly, in his opinion, the best. It could be more accurately adapted to larynxes of varying sizes, and was much less likely to injure the parts either by undue pressure or by difficulty of introduction. In one case, in his attempts to introduce a Hahn cannula, the rings of the trachea were considerably torn. The objections to Trendelenburg's cannula were: arrest of respiration, which sometimes followed its introduction; the production of pressure gangrene in the trachea; obstruction to the lower end of the tube by the rubber ballooning into the trachea beneath it; the bursting of the rubber or its being cut; and, if none of these mishaps occurred, the air often gradually escaped and thus rendered the cannula useless. The Hahn cannula could not be made aseptic so easily as the others; and, as Lennox Browne has pointed out, sometimes twenty minutes were required for the expansion of the sponge after its introduction.

Anæsthesia: This was done at first through the mouth, and was so continued until the larynx or trachea was invaded. A large tracheotomy cannula (12 mm. in diameter) was then introduced, and held in place by disinfected tapes tied around the neck. The inner tube of this cannula was removed and the metal tube of a Hahn cannula, which precisely fitted it, was introduced. A rubber tube connected this with the ordinary funnel for the administration of chloroform.

The operation proper: The speaker described the operation in connection with the case reported, and then indicated the improvement in technique which he purposed adopting in the next case he might have.

The after-treatment: (*a*) Posture: The patient was kept in the Trendelenburg position by placing a chair under the foot of the bed. This posture prevented any wound fluids from running down (or rather up) into the lung. This position was to be maintained for one day. On the second day the bed was lowered to the horizontal plane. On the third day the patient was allowed to sit up in bed on a bed-rest; on the fourth, to get out of bed and sit in a reclining chair, and on the fifth day he might walk about the room. (*b*) Food: For two days nutritive enemata only were to be used. After that a teasponful of liquid food was given, at first every half-hour, always followed by a tablespoonful of sterile water to wash away any food that might possibly leak into the laryngeal wound. At the end of a week full diet as to quantity might be allowed, but no solid food was to be given until the tenth day. No catheter or œsophageal tube was required. The patient in the case presented could swallow from the very first. (*c*) Dressing: The primary dressing was described in connection with the case. On the day after the operation the small gauze drain was to be removed. Half of the stitches might be taken out on the fourth day, and the remainder on the sixth day. In the case reported the temperature on the day after the operation rose to 101.8° F., and fluctuated between the normal and 101° for a week, when it fell to the normal.

Objections: The only objection to this method which occurred to the author was, that it absolutely precluded the use of any artificial larynx. But the possession of voice is nothing when compared with a speedy recovery and a greatly diminished danger of a fatal result. Rutsch believed such a larynx was very unsatisfactory. Of course, the author recognized the fact that one case did not prove the value of any method, but its advantages were so striking in this case that, as laryngectomy was a relatively rare operation, he had not thought it best to wait until he could accumulate a much larger experience before bringing it to the attention of the profession.

Final results: Of course, it was too early yet to draw any inference as to the possibility of recurrence in this particular case; nor was this his purpose. His intention had been rather to demonstrate a method of laryngectomy which would diminish more especially the immediate mortality of the operation and secure speedy recovery by primary union. The chances of recurrence were no greater, nor yet any less, after operation by this method than by any other. This particular patient had been able to go out in all weathers during the past extremely severe winter, though living as far north as Waterville, Me., where the thermometer had been many degrees below zero.

At the conclusion of the president's address, a symposium on "The Surgery of the Spanish War" was begun.

**The First-Aid Package in Military Surgery.**—This paper was read by Dr. Nicholas Senn, of Chicago. He stated that two things were brought out clearly during the Russo-Turkish war, namely, the value of a first-aid antiseptic occlusive dressing in the prevention of wound infection, and the importance of immediate immobilization of compound gunshot fractures. Dr. Senn suggested the following first-aid package for field use and emergency work: Two pieces of lintin, a form of compressed cotton, four inches wide and sixteen inches long, sterilized and folded twice lengthwise; a teaspoonful of boro-salicylic powder in a small, waxed, aseptic envelope; between them a piece of sterile gauze, forty-four inches square, with two safety-pins, folded to corresponding size with the lintin compress; all of these articles wrapped in tinfoil; two strips of rubber adhesive plaster, an inch wide and eight inches long; the whole to be sewed in an impermeable canvas or linen cover. In using the package the powder was applied to the wound, when the lintin was used as a compress and held in place by the strips of adhesive plaster and the gauze bandage over it. If two wounds were to be dressed at the same time, as was usually the case in modern warfare, the contents of the package were equally divided and used, which could be done without materially impairing the efficiency of the dressing. The slight hemorrhage in wounds inflicted by the small-calibre bullet would soon saturate a part of the dressing, which by evaporation would convert the antiseptic powder and the cotton into a dry antiseptic crust, the very best protection for the wound against infection. Many military surgeons had expressed themselves recently as being opposed to the employment of the first-aid package by any one except medical men. This position Dr. Senn thought would be found untenable during any great war, since the number of wounded would greatly exceed the working capacity of the limited number of surgeons.

In summarizing, the following conclusions were emphasized: (1) First-aid packages were indispensable on the battlefield in modern warfare. (2) The first-aid dressing must be sufficiently compact and light to be carried in the skirt of the uniform, or on the inner surface of the cartridge or sword belt, in order to be of no inconvenience to the soldier or in conflict with military regulations. (3) The Esmarch triangular bandage was of great value in the school of instruction, but in the first-aid package it was inferior to the gauze bandage. (4) The first-aid package must contain in a waxed aseptic envelope an antiseptic powder, such as boro-salicylic powder, sterilized pins wrapped in tinfoil, and between this package and the outside impermeable cover two strips of adhesive plaster an inch wide and eight inches long. (5) The first-aid dressing must be applied as soon as possible after the receipt of the injury, a part of the field service which could be safely entrusted to competent hospital-corps men. (6) The first-aid dressing, if employed behind the firing line, should be applied without re-

moval of the clothing over the injured part and fastened to the surface of the skin with strips of rubber adhesive plaster, the bandage being applied over and not under the clothing. (7) The first-aid dressing must be dry and should remain so by dispensing with an impermeable cover over it, so as not to interfere with free evaporation of the wound secretion. (8) The first-aid dressing should not be disturbed unnecessarily, but any defects should be corrected at the first dressing-station.

**The Battleship in War.**—A paper on this subject was read by Dr. N. M. Ferebee, medical inspector of the United States navy, Norfolk, Va. He described a modern battleship, and spoke of the preparations for, and the conditions during, war. He also narrated his experiences with modern rifle bullets and with shells, and closed his paper by detailing interesting cases.

**The Organization and Equipment of Military Field Hospitals.**—Dr. George R. Fowler, of Brooklyn, read this paper. Under the head of organization, the essayist dealt with executive offices, dispensary, property office, post-office, quartermaster's office, commissary office, medical ward, surgical ward, operating tent or pavilion, pathological and bacteriological departments, cooking department, diet kitchens, sanitary and disinfection departments. In referring to location and arrangement, he spoke of the importance of selecting a suitable site, and then dwelt upon soil, drainage, arrangement of the wards and sinks, and emphasized the importance of cremating garbage and typhoid excreta. In referring to equipment, he spoke of tentage, pavilions, furniture, linen, medical supplies, anæsthetics and antiseptics, instruments, sterilizers, operating-tent furniture, ligature and suture materials, dressing-materials, splint materials, and transportation facilities. Lastly, he dwelt at length upon the personnel, which comprised executive and administrative officers, professional staff, ward officers, operating-staff, ophthalmologist, aurist, dentist.

**The Effects of Modern Small-Arm Projectiles as Shown by the Wounded of the Fifth Corps.**—This paper was read by Dr. Charles B. Nancrede, of Ann Arbor, Mich. Reports showed that about fourteen hundred wounded were cared for at the hospital with which he was connected, for nearly all of the injured in this corps who survived for twenty-four hours sooner or later passed through their hands, so that flesh wounds and those of a day to a week or more were observed. Flesh wounds were always of a trivial nature, unless the ball became deformed by striking some extraneous object, or when stripping its mantle, as it sometimes did. This immunity enjoyed by the flesh wounds caused by Mauser and Krag balls resulted, first, from the slight amount of contusion caused by the rapidly moving ball; second, the aseptic condition of the ball; third, the rarity of the carriage of fragments of clothing into the wound, as was not uncommonly done by the 43-calibre Remington, brass-mantled balls. If they were kept aseptic, the majority of flesh wounds healed almost as if they had been incised wounds, not uncommonly cicatrizing under the primary field dressing made with the first-aid package. Contusions, or slight wounds of the great vessels leading to so-called traumatic aneurisms, or aseptic or septic sloughing of the vessels many days after the receipt of the wound, were far from uncommon. Thus, he saw one wounded subclavian artery when the patient survived over three weeks, to succumb finally to hemorrhage during an attempt to ligate the vessel, which was torn for a long distance. He also knew of another patient dying on the table some weeks after being wounded, during an attempt to secure the same vessel. He tied the common femoral for wounds and assisted a colleague in securing another, days after the receipt of the injury. He tied one radial for secondary hemorrhage and ordered the tying of an ulnar for ball injury, several days after their division, and was compelled to amputate an arm after failing to secure a bleeding brachial in an apparently aseptic wound, two weeks after the man had been shot. The greatest advance in military surgery on the battlefield in recent times was the first-aid packet, and the greatest boons conferred on the wounded soldier had been asepsis and antisepsis, because in the majority of instances they rendered his injuries so painless and their complications so slight, that even anæsthetics no longer occupied the chief place as a blessing to the wounded, because they were comparatively rarely needed. Antiseptic occlusion also proved the best treatment for most of the thoracic, abdominal, and articular injuries. All patients with perforating ball wounds of the abdomen, who were operated upon, he was informed, perished, while a number he saw recovered without intervention, antiseptic occlusion being relied upon. Wounds of the liver and kidneys did not seem to give rise to dangerous infection in the small number treated. If section could not be done before peritoneal infection had become well established, both civil and military surgeons had long believed that, poor as are the chances of recovery, they were lessened rather than increased by the operation.

**Appendicitis: (*a*) Should Every Case be Operated upon as Soon as the Diagnosis of Appendicitis is Made? (*b*) Should the Appendix be Removed in Every Case?**—Dr. M. H. Richardson, of Boston, read a paper on this subject. At the bedside, in a specific case of appendicitis, there would be doubtless little difference of opinion even among those surgeons who seemed to differ materially in the expression of their views. What one might describe as a severe case another might regard as a mild one; what one considered a hopeless infection another considered only a desperate one, and so on. The conclusions arrived at by the speaker were the result of experience in more than nine hundred cases, personally observed and treated, and of personal observation of many others in the practice of hospital colleagues. The total number was 904. In 259 operations in acute cases, 72 were fatal; 4 of these deaths were in the hands of other surgeons; 189 acute cases were not operated upon. Of these, 31 were fatal, probably all moribund at the time of first examination. The total operations were 569, of which 238 were interval operations without a death. The total number of operations in the acute stage was 331; mortality in acute stage, 21.5 per cent. Many of these fatal cases were desperate ones. All were severe. The mortality in acute cases without operation was fully 31 in 189 cases. But practically in all these fatal cases the patients were moribund and hopeless when first seen. Had all acute cases been operated upon, the mortality after operation would have been reduced, because in most of the acute cases not operated upon the patients would have recovered also with operation. In fact, most of these were operated upon in the interval. Deductions from mortality tables were misleading. It would be as unfair to conclude, because a long series of bad cases had ended in death after operation, that therefore no operation should ever be performed, as to conclude that because practically all the reader's acute cases unoperated upon terminated in recovery (excluding the moribund), therefore no operation was ever necessary. There was a wise middle course by which unnecessary operations were avoided and necessary ones were performed. In the initial stage severe symptoms of onset demanded immediate intervention. These symptoms were pain, vomiting, tenderness, rigidity, shock—those common to most acute abdominal emer-

gencies. In many cases these symptoms would subside, but the general trend of a case could not be determined at one observation. Exploration was therefore indicated. The surgeon must expect often to find other lesions than appendicitis at the initial stage, but lesions quite as important and often demanding intervention even more urgently. Cases of mild onset might well wait until a second observation showed the probable course of the case. Time thus spent was wisely spent. The most important question was not whether to operate in appendicitis, but rather when to operate. In view of the great mortality after operation in severe cases, of the disadvantages following the drainage necessary in septic cases, weakness of muscles, stretching of scars, hernias, and the like, the best time to operate was in the period of perfect health following the attack. In a large percentage of acute cases, recovery from the acute attack would take place, and operation could be safely performed through a small incision which would not weaken the abdominal wall. Cases must not be watched, however, unless there are reliable signs of convalescence. After the initial stage the question of intervention became more difficult. When observed for the first time on the second, third, or fourth days, severe cases should be operated upon at once, unless they were improving so rapidly that there was a strong expectation of complete recovery and interval operation. Intervention was still more strongly indicated if the symptoms were increasing in severity. Operation was indicated, too, if the symptoms after marked improvement recurred, as if, though moderate, they were not improving. In the consideration of symptoms after the early hours, the character and extent of pain, tenderness, and rigidity were important as determining the width and depth of the area of infection. The constitutional signs were less reliable than the local; they might be deceptive guides. The chief objection to operating in every case was the danger of converting a localized into a general infection. Every case in which at the time of operation there was an uninfected general peritoneal cavity and in which the patient died with general infection after operation (and these were more numerous than were known) excited doubt as to the wisdom of operating in all cases. It was known that very many patients with localized peritonitis recovered and were successfully operated upon in the interval, and cases showing improvement in an enormous proportion went on to recovery and intermediate operation. If the patient was improving with a successfully localized peritonitis of considerable extent, especially if it was centrally localized, as in the pelvis, operation should be postponed until intervention could be safely practised, because these cases comprised, in the absence of general peritonitis, the most dangerous ones. Moreover, intervention became safer with a few hours' or days' delay in improving cases; first, because the general exudate, so easily infected during operation, became absorbed; second, because the local exudate diminished in size; third, because walling off with gauze was practicable when the adhesions were firm, impossible when they were thin; fourth, operation ruptured at once the localized peritonitis, and started the too often fatal peritonitis. Moreover, the patient's general strength improved with the local improvement. When there was a tumor situated to the right side, or directly under the abdominal wall, so that walling off with gauze was practicable, operation might be performed under conditions that would contraindicate intervention when the tumor was centrally located or in the pelvis.

In cases that were very far advanced nothing should be done, for the reason that the simplest active intervention would turn the scales against the patient. In areas with firm walls, simple drainage by a small incision was preferable to removal of the appendix because of the risk of causing general infection by separating adhesions. Of one hundred and five cases of simple drainage, all recovered but two. Many were operated upon subsequently for hernias and for removal of the appendix. An attempt should always be made to remove the appendix whenever the peritoneal cavity was opened, unless the patient's condition forbade prolonged search. In many cases of abscess with firm walls, a slough would be found which on examination would prove to be a necrosed or exfoliated appendix. In such cases no subsequent operation for removal of the appendix would be necessary. If, after recovery from simple drainage in acute appendicitis, there was evidence of renewed appendicular trouble, the appendix should be removed, the scar of the original wound incised, and the wound carefully closed. This operation was especially desirable if there was hernia in the scar, or even stretching or discomfort. Hernia of itself, after all operations for acute appendicitis, should be operated upon if it caused discomfort or disability. In very rare instances there might be a recurrence of infection in the region of the ileo-cæcal valve, even after removal of the appendix. In the speaker's experience two such cases had been noted, one resulting in recovery from operation, the other requiring drainage.

The discussion on Dr. Richardson's paper was opened by Dr. John B. Deaver, of Philadelphia, who said that the paper had brought out many points on appendicitis about which an active warfare had been waged for some years. Upon the surgeon's individual decision at the bedside often depended the life of the patient, and in every case the very points with which the paper dealt had to be faced and a decision made. As to the question whether every case should be operated upon as soon as the diagnosis was made, his answer was, Yes, with two exceptions: First, acute active general peritonitis; second, collapse. Should the appendix be removed in every case of appendicitis? Yes, with the exception of those cases in which the bowel forming a part of the abscess wall had undergone necrotic changes, rendering the bowel friable and apt to rupture during the necessary manipulation. Dr. Richardson had most wisely divided his first heading into two classes, those in which the diagnosis had been made in the early hours—and the speaker took it for granted that he meant within twenty-four hours—and those in which a diagnosis was made after this period of time had elapsed. In answer to the first question, Dr. Deaver asserted most emphatically that the early hours was the time *par excellence* for operation in this most serious of intra-abdominal affections: First, because practically all patients operated upon at this time got well or at least gave the lowest mortality, this mortality increasing with the interval between the onset of the attack and the time of operation. Thus, of eighteen cases operated upon within the first twenty-four hours, only one was fatal, a mortality of 5.5 per cent. Of thirty acute cases, on the other hand, operated upon within forty-eight hours, ten resulted in death, a mortality of 33.3 per cent. So far as his experience went, a careful examination of the statistics of acute cases convinced him that the local pathological changes reached by progressive stages their severest limit within the first forty-eight hours, and after that period the changes were more in the nature of sequelæ following the primary stage of infection. Second, the percentage of patients that had one attack and then remained perfectly well and free from other attacks was very small. Of four hundred and sixty of his own patients, three hundred and twelve had more than oen attack. In fact, it seemed to him unjustifiable to offer a patient the faint hope of any attack of appendical inflammation being the last.

Should we operate when the diagnosis is made after

the early hours if the symptoms are severe? He would say that his experience had led him to the belief that symptoms were very unreliable and were not in proportion to, nor do they indicate, the severity of the pathological processes which were taking place in the abdomen. Many times he had opened the abdomen of a patient with a normal temperature, flat belly walls, and a quiet, retentive stomach, in whom tenderness on deep pressure was the only sign of persistent trouble, and had found pus or a gangrenous and perforated appendix. The surgeon who waited in the case of appendicitis for the appearance of severe symptoms, or, worse yet, waited until the symptoms increased in severity for an indication to operate, would have many unnecessary deaths to his credit.

Should the appendix be removed in localized abscess with firm walls? The success in the removal of the appendix in a localized abscess with firm walls depended upon the skill and the technique of the surgeon. Under these conditions the appendix should be removed, the only occasion for a difference of opinion being as to the time of its removal, *i.e.*, at the primary operation or at a subsequent operation. If the appendix could be removed at the primary operation without additional risk to the patient, it seemed to him that this was the time of election. That it could be done without additional or any risk had been repeatedly demonstrated, and in his own practice he did it in nearly all cases, because in two hundred and fifty-seven primary removals his death rate in the past had been 16.7 per cent., and in thirteen secondary removals the death rate was 30.7 per cent. The reasons for the removal under these conditions were that surgeons did not subject their patients to the danger of an attack of acute appendicitis occurring before the secondary operation. There was less likelihood of fistulæ, either fecal or simple. The patient was cured with one operation instead of two, with the consequent saving of a variable period of invalidism for the patient. When a patient's strength did not permit a prolonged search for the appendix, it should not be necessary. The appendix could hold but one of a few positions: it must be either post-cæcal, pointing into the pelvis toward the spleen, or confined in the ileo-colic or sub-cæcal or ileo-cæcal fossa. If the appendix was embedded in exudate, the exudate itself would indicate its position. He agreed with Dr. Richardson as to the necessity of the ultimate removal of the appendix, differing from him only in the length of time before the complete operation should be performed.

Dr. Christian Fenger, of Chicago, indorsed in the main nearly everything that Dr. Richardson had said. He, however, disagreed almost entirely with the views expressed by Dr. Deaver.

Dr. Francis B. Harrington, of Boston, thought there was very little difference of opinion between Dr. Richardson and Dr. Deaver. He said that Dr. Deaver did not operate on every case; he considered the condition of the patient. If the patient was in collapse he waited, and so did all surgeons. It was better to wait not only in cases of collapse but in other instances. He liked to remove the appendix in every case when it was possible to do so. On the other hand, there were certain conditions in which he was inclined to wait perhaps twelve or twenty-four hours, or even longer, before operating.

Dr. S. H. Weeks, of Portland, Maine, considered the teaching of Dr. Richardson safe. It must be remembered that most of the members were teachers of surgery, and it was unsafe to instruct students to operate and remove the appendix in every case.

Dr. Joseph Ransohoff, of Cincinnati, thought the doctrine advocated by Dr. Deaver would do a great deal of harm, if followed by most men who operated upon cases of appendicitis. An important point to remember was this, that five-sixths of the operations for appendicitis were performed by general practitioners, men who had had very little experience in handling the intestines, in dealing with abscesses within the cavity of the abdomen, etc.

Dr. Nicholas Senn, of Chicago, said uniformity of practice in the treatment of appendicitis would never probably prevail. Each man formulated his own indications and followed his own rule of practice. Personally, he felt weakest in making an early diagnosis in the first attack. Dr. Senn narrated two instructive cases in which it was extremely difficult to make a differential diagnosis between perforative appendicitis and perforative typhoid ulcer, one of the cases being that of an honored colleague.

Dr. J. S. Conner, of Cincinnati, believed it was not wise to be governed in surgical judgment by the citation of one or two cases; neither was it wise to neglect the warning of a single case. While he did not operate on all cases, he believed in operating on suitable cases, and at the proper time if it could be had.

Dr. Dudley P. Allen, of Cleveland, removed the appendix in an increasing number of cases, but of those cases of abscess with sloughing of the wall in which he had not removed the appendix, he recalled but three that did not heal of themselves. He had seen fecal fistulæ follow a considerable number of cases, some of which had persisted, but others which had healed of themselves.

Dr. Richard H. Harte, of Philadelphia, favored the removal of the appendix in cases of early operation. He thought that conservatism in the treatment of this disease was a great mistake, and maintained that in nine cases out of ten the appendix could be successfully removed.

The discussion was further participated in by Drs. H. H. Mudd, Joseph W. Hearn, B. F. Curtis, and N. B. Carson, all of whom substantiated in the main the views taken by the essayist.

**On Some Conditions of Healing by First Intention, with Special Reference to Disinfection of the Hands.**—This paper was contributed by Dr. Theodor Kocher, of Berne, Switzerland, and was read by the secretary in the absence of its author. The conclusion of the author as to the possibility of securing primary union of operation wounds with or without gloves is the following:

"1. Either, do use sterilized rubber gloves for every operation when you wish to be quite independent as to the form of your nails, the touching of everything you like, and the liberty to wash or not to wash your hands, and when you can spend plenty of money. Put your covered hand from time to time in a strong antiseptic solution (best, two-per-cent. sublimate) during a long operation if you wish to be very careful.

"2. Or, never wear gloves for operations; do what you like between your operations, but poison yourself every time before you operate by brushing and bathing your hands for ten minutes in a strong, hot sublimate solution after thorough washing and cleansing with hot water, soap, and alcohol for fifteen minutes. Repeat a short antiseptic ablution frequently during a long operation, when you wish to be very careful.

"3. Or, go the golden middle way; avoid touching with uncovered hands any infective or septic material between the operations, or wash it carefully away at once; cut your nails as short as possible; brush your hands thoroughly with hot water, soap, and alcohol (eighty-five to ninety-five per cent.), avoiding any poisonous disinfectant before you operate, and, if you wish to be very careful, put cotton, silk, or, best, rubber gloves on when you touch the threads for ligatures and sutures, and when you have much to tear the tissues and to rub your fingers in the depth of a wound.

"4. But don't forget that the healing of the wounds *per primam intentionem* does not depend exclusively upon your hands, but also upon the same preparation of the patient's skin, upon sterilization of everything else coming in contact with the wound and its surroundings, upon complete arrest of bleeding, exact closing of the wound by sutures, or avoiding accumulation of fluids in cavities, necessarily left, by drainage, and last but not least, upon the use of antiseptic threads for ligatures and sutures, as long as impermeable threads are not yet invented."

**Nephrectomy versus Nephrotomy.**—Dr. Joseph Ransohoff, of Cincinnati, read a paper on this subject. He said that renal surgery was essentially the product of the past twenty years. The occasional operations on the kidney performed before that time paved the way for a clearer appreciation of the conditions demanding operative relief. Improvements in the mode of examination, and the consequently greater accuracy in diagnosis, the recognition of the early gross changes wrought by disease, as seen by operation rather than by autopsy, and the comparative safety of incisions through healthy kidney tissue, had brought to the fore the element of safe conservatism in the domain of renal surgery. The speaker reported several interesting and instructive cases of pyonephrosis. Nephrotomy, *per se*, was doubtless an operation nearly devoid of danger. When performed on a healthy kidney, as for stone, the mortality was less than five per cent. When performed for suppurative diseases, the mortality rose. He had tabulated records of 78 nephrotomies for pyonephrosis exclusive of tuberculosis published within the last three years from various clinics. Of these 78 nephrotomies, 17 were followed by death, a mortality of 21.8 per cent. In the hands of some surgeons the mortality has been very large. Four out of five cases were fatal in the Vienna clinic. Out of 6 cases of nephrotomies at the Roosevelt Hospital, 3 died. On the other hand, Israel lost only 1 out of 8, and Thornton 1 out of 12. From the same sources he had tabulated 37 primary nephrectomies with 9 deaths, giving a mortality of 24.3 per cent., and 17 secondary nephrectomies, with 7 recoveries and 10 deaths, a mortality of 58.8 per cent.

The advantages of nephrotomy for pyonephrosis were obvious: First, it was an operation readily tolerated even in patients greatly reduced by fever. Second, it permitted the surgeon to determine the condition of the opposite kidney. Third, by it the saving of even a small amount of functionating kidney tissue might throw the balance in favor of recovery. In dealing surgically with a pyonephrotic kidney, statistics could guide the operator only in a general way in the choice between nephrectomy and nephrotomy. Nephrotomy was indicated in pyonephrosis, first, when the condition of the opposite kidney could not be ascertained. Second, when the reduced condition of the patient would not permit the major operation if this was indicated. The nephrotomy was then but the preliminary step, to be followed by nephrectomy as speedily as possible. Third, when the operation revealed the presence of considerable kidney tissue, and an approach to the normal on the part of the pelvis and proximal portion of the ureter. Here a later ureteroplasty might avert the need of nephrectomy. Fourth, when there was evidence or suspicion of disease in the other kidney. Primary nephrectomy was indicated, first, when there was a sound second kidney; second, when inspection of the exposed kidney showed many or large pouches that could not be successfully drained; third, when there was little kidney tissue left; fourth, when an examination of the pelvis and proximal portion of the ureter made it reasonably certain that a return to the normal could not take place; fifth, in para- and peri-nephric suppurations in which the kidney acted as a valve impeding successful drainage (Israel).

**Hernia following Operations for Appendicitis.**—This paper was read by Dr. Francis B. Harrington, of Boston. He said that he had made a personal examination of the condition of the abdominal wall in 236 cases of appendicitis which had been operated upon at the Massachusetts General Hospital by various surgeons. They represented all varieties of the disease. The period which had elapsed since operation varied from nine months to nine years. No case was included which was operated upon since July, 1897. Total number examined, 236; males, 190; females, 46; 27 true hernias in all—11.5 per cent.; 21 true hernias in males—11 per cent.; 6 true hernias in females—13 1/3 per cent. Eighty-five wounds closed at the time of operation, 3 hernias, 3.5 per cent.; 85 wounds partly closed at the time of operation, 11 hernias, 12.5 per cent.; 63 wounds left entirely open at the time of operation, 13 hernias, 20 per cent. If with these cases of true hernia were included 10 cases of punctiform hernia and 53 cases of more or less bulging in the scar which did not constitute true hernia, the following percentage of weak scars was noted: In 85 closed wounds, 6 per cent.; in 88 partly closed wounds, 51 per cent.; in 63 open wounds, 62 per cent.

Inter-muscular spaces: An opening between muscles or tendons, or both, could be detected in the scars —in 85 closed at the time of operation, 26 per cent.; in 88 partly closed at the time of operation, 83 per cent.; in 63 open wounds, 87 per cent.

General abdominal bulging: In 85 closed incisions, 7 per cent.; in 88 partly closed incisions, 45 per cent.; in 63 open incisions, 46 per cent.

During the period in which these cases were operated upon, *i.e.*, from 1888 to 1897, some of the muscles or tendons were cut at right angles to their fibres in the acute cases, and often in the cases in which the incisions were tightly closed at the time of operation. The speaker advocated the use of an enlarged McBurney incision in all acute cases, which would obviate the cutting transversely of any muscle or aponeurosis.

*Résumé:* Hernia and bulging occurred frequently after operations for appendicitis, and resulted from the separation of muscles and other tissues in the scar. They were more common when drainage had been used. The muscular and tendinous tissues should not be transversely cut in any appendix operation unless it was unavoidable. As little drainage material as safety would permit should be used and, when necessary at all, the wound should be closed as far as possible with sutures, and the drainage removed early. If the wound could be closed immediately, the tissues should be restored to their normal position by suturing each layer. Stout belts and trusses were of little value in preventing hernia, and might even do harm. The abdominal muscles from the earliest period possible after operation should be developed by appropriate muscular exercises. If hernia or marked bulging appeared, operation for cure was safe and satisfactory.

**Some Unusual Cases of Appendicitis with Complications.**—Dr. Albert Vander Veer, of Albany, N. Y., read this paper. He said that operative surgery, in its relation to the appendix, would ever present rare and unusual cases. This was brought out strongly last year, when the president of the association and others gave the histories of some very unusual lesions of the abdomen. Surgeons might examine their cases with ever so much skill, employing diagnostic intelligence to the best advantage, yet when they entered the peritoneal cavity they must be prepared for surprises. From the knowledge acquired from these isolated and rather rare cases, it was more possible to increase the percentage of recoveries. A hernial sac with the appendix therein was not particularly rare, but to find an

appendix containing a foreign substance like a pin, which had not caused trouble, was somewhat unusual. To operate for the relief of femoral hernia and find not only the appendix but a prolapsed bladder, in the female, was certainly decidedly rare. Dr. Vander Veer then detailed eight somewhat unusual and complicated cases.

Dr. Solon Marks, of Milwaukee, Wis., reported an interesting case of forward dislocation of the fifth cervical vertebra.

**Cases of Fracture of the Skull followed by Recovery.**—Dr. Dudley P. Allen, of Cleveland, Ohio, presented this paper. He reported ten cases of fracture of the skull, all but one of them involving the base. The first five reported were fractures at the base of the skull without any injury to the vault. Of these patients, three were rendered totally unconscious at the time of the accident, one was in a semi-conscious condition, and the third, so far as could be ascertained, retained consciousness. Bleeding from both ears occurred in two of these cases, whereas in three of the cases there was bleeding at only one ear. Deafness in one case occurred in both ears at the time of injury. Whether in the other cases deafness occurred at the time of injury could not be definitely determined. In two of these cases, however, deafness was complete and permanent in one ear, and in one case the hearing was much impaired in one ear. Loss of smell was complete in one case and greatly impaired in one case. Paralysis of one side of the face occurred in two cases, in one of which it remained permanent. The five persons in whom the fracture was confined to the base of the skull were alive and well at the present time, except for the disabilities just described. There were two cases of children who fell from heights upon the vault of the skull, causing most extensive fracture and great deformity of the cranium. In one of these there was a great deal of hemorrhage from the ears. In both the scalp was lifted, the cranium was laid bare, and by means of a hook the fragments making up the depressed vault were raised to their normal positions. Both patients had recovered; one, however, had impaired hearing in one ear. In two cases reported injuries were received in the frontal region extending into the base. In one of these there was extensive injury to the frontal bone, and a large amount of bone and considerable lacerated brain tissue were removed. There was a fracture in this case extending across above the frontal eminence to the temporal fossa upon the side of the skull opposite to that which received the greatest injury, and there was a fissure from the base of the skull extending from the frontal bone backward to the sella turcica. In this case there was a large cerebral hernia. In the other case the injury to the frontal region and the involvement of bone were small. The point of interest in the latter case was the temperature, which rose gradually at two different periods to 105° F., the case presenting many of the symptoms of typhoid fever with a relapse of the same. The other characteristic symptoms of typhoid fever were, however, entirely lacking, and the presence of optic neuritis, indicating probably a basal meningitis, placed the diagnosis of the cause of fever in considerable doubt. In both cases a complete recovery took place. The tenth case was one of severe injury in the region of the right parietal bone, followed in some weeks by impairment of mental activity, and also of motion of the right arm and leg. This was found to be due to a large subdural collection of blood upon the left side, notwithstanding there was no evidence of injury upon this side. The accumulated blood amounted to several ounces. It was removed and the patient was now well. These cases in which recovery took place were reported because of the interest attached to the symptoms attending fracture, namely, hemorrhage from the ears, facial paralysis, loss of hearing, and loss of smell.

Dr. W. Joseph Hearn, of Philadelphia, reported an interesting case of removal of an œsophageal diverticulum. In the discussion Dr. M. H. Richardson, of Boston, narrated two interesting cases.

The following officers were elected for the ensuing year: *President*, Dr. Robert F. Weir, of New York City; *First Vice-President*, Dr. Charles B. Nancrede, of Ann Arbor, Mich.; *Second Vice-President*, Dr. Edmond Souchon, of New Orleans; *Secretary*, Dr. Herbert L. Burrell, of Boston; *Treasurer*, Dr. George R. Fowler, of Brooklyn, N. Y.; *Recorder*, Dr. De Forest Willard, of Philadelphia; *Member of the Council*, Dr. W. W. Keen, of Philadelphia.

Washington, D. C., was selected as the next place of meeting, in conjunction with the Congress of Physicians and Surgeons, on May 1, 2, and 3, 1900.

## AMERICAN MEDICAL ASSOCIATION.

*Fiftieth Annual Meeting, held at Columbus, Ohio, June 6, 7, 8, 9, and 10, 1899.*

### SECTION ON LARYNGOLOGY AND OTOLOGY.

Emil Mayer, M.D., of New York, Chairman.

*First Day—Tuesday, June 6th.*

**Chairman's Address.**—The chairman, Dr. Emil Mayer, of New York City, presented the annual address. He spoke of the advances made in otology by the early recognition of brain abscesses and sinus thrombosis, and of their cure by operation. The greatest advance in rhinology had been in the discarding of the galvano-cautery. He presented the most recent device for intubation in cases of chronic stenosis of the larynx, the invention of Dr. John Rogers, of New York. It consisted of an intubation tube of the O'Dwyer pattern, with an opening made directly opposite the tracheotomy wound, as preliminary tracheotomy was nearly always requisite in these affections. Into this opening was screwed a solid plug of hard rubber, thus effectually preventing its being coughed out. The speaker closed his address with an appeal for the greater recognition, during their lifetime, of those medical benefactors to their race who, like O'Dwyer, Wilhelm Meyer, and others, had been too little appreciated.

**Tuberculosis of the Pharynx and a Preliminary Report of Tuberculous Infection of the Tonsils and the Lymphoid Tissue of the Pharynx.**—Dr. Clement F. Theisen, of Albany, read this paper. In it he reported two cases of primary tuberculosis of the pharynx, both verified by bacteriological examination. One of the patients died, the other recovered. Of twelve hypertrophied tonsils and twenty-three adenoid masses removed and examined at the Bender Laboratory, two of the tonsils had shown the presence of tubercle bacilli, though none had any evidence of tuberculosis.

**Accessory Thyroid Tumors at the Base of the Tongue.**—Dr. J. Schadle, of St. Paul, read a paper on this subject. The tumor had existed for six months prior to first coming under his observation. It had been situated at the base of the tongue, and had swollen and become vascular during the time of apparently suppressed menstrual function. Under electrolysis it had diminished to one-third of its original size, but copious bleeding had eventually necessitated a discontinuance of this treatment. It had been finally extirpated by an operation performed by Dr. Charles McBurney. The growth had proved to be a gland of the thyroid.

**Observations in Three Hundred Tonsillectomies.**—Dr. J. Homer Coulter, of Chicago, read this paper. He said that the marked improvement which almost universally followed a tonsillectomy, or even a tonsillotomy, should be sufficient confirmation of the harm usually caused by hypertrophied tonsils. The writer made a strong plea for total extirpation of the tonsil, which was the operation performed by him in all of these cases. These tonsillectomies had been done by means of the galvano-cautery, and had been in the nature of bloodless dissections. He claimed that the general result of tonsillectomy was a cosmetically and physiologically perfect throat, and that this was attained as follows: (1) By liberating and allowing perfect action of the pillars and soft palate; (2) by the removal from the pharynx of mechanical obstruction to the sound waves; (3) by the entire removal from the throat of the possibilities of toxin absorption by the tonsillar gland; (4) by leaving a smooth surface in the seat of the tonsil; and (5) by causing a disappearance of pillar hypertrophy. Tonsillectomy was more likely to remove a reflex neurosis, due to a pathological tonsil, than was a tonsillotomy. If it was thoroughly done, it would leave a smooth surface, which was not so often the case after tonsillotomy, and was practically impossible after ignipuncture. To singers this was a matter of some importance. Moreover, tonsillectomy was feasible in certain cases in which tonsillotomy would be almost an impossibility.

**The Value of Muscle Training in the Treatment of Vocal and Speech Defects.**—Dr. G. H. Makuen, of Philadelphia, read a paper with this title. The direct cause of vocal defects, he said, was always a faulty musculation in the vocal mechanism. While the intrinsic muscles of the larynx were, for the most part, involuntary, the extrinsic muscles might be brought under the direct control of the will and the intrinsic muscles controlled thereby. The importance of a correct position of the larynx could hardly be overestimated. These muscles might be brought under the direct control of the will either collectively or in pairs. At the request of the chairman, Dr. Makuen demonstrated his method of controlling the extrinsic muscles.

**The Prognosis of Laryngeal Tuberculosis.**—Dr. Robert Levy, of Denver, read this paper. He expressed the opinion that properly chosen surgical or medical treatment might greatly influence the prognosis of this disease, and stated that, in his experience, those cases in which the epiglottic or aryepiglottic folds, or both, had been involved had yielded the worst prognosis.

**The Treatment of Chronic Croup.**—Dr. Edwin Rosenthal, of Philadelphia, read a paper on this topic. He stated that he had frequently seen stenosis occur in cases in which intubation had been performed and the tube removed ten days after apparent recovery. It was also seen when no intubation had been performed, and when all was apparently well. In one case, seen by him, of stenosis existing five weeks after an attack of diphtheria, only streptococci had been found. The symptoms of stenosis had subsided promptly after an injection of 10 c.c. of antistreptococcic serum. The streptococcus infection might alone prove sufficient to produce croup. He had seen peroxide of hydrogen produce croup secondarily to other varieties of diphtheria. In one case of diphtheria he had used twenty thousand units of antitoxin. It was his custom to use antitoxin immediately, and, if streptococci were found, to use the antistreptococcic serum also.

**Colds.**—Dr. Ephraim Cutter presented a communication with this title.

**Infective Granulomata of the Pharynx.**—Dr. Emma E. Musson read this paper. She reported a case of infective granulomata of the pharynx due to the bacillus mallei. It had been repeatedly reported as a sarcoma by microscopists, and only finally, when a bacteriological examination had been made, had the cause, glanders, been ascertained. She had never found any clew to the method of infection. Death had resulted, but the direct cause was not stated.

---

*Second Day—Wednesday, June 7th.*

The morning was devoted to a joint session of the sections on ophthalmology and on laryngology and otology. The subject for discussion was "The Relation of Ocular Diseases to Affections of the Nose and Neighboring Cavities." Dr. Charles Stedman Bull, of New York, discussed "Some Points in the Symptomatology, Pathology, and Treatment of the Sinuses Adjacent and Accessory to the Orbit" (see page 73). Dr. J. H. Bryan, of Washington, D. C., took up the "Diseases of the Accessory Sinuses in Their Relation to Diseases of the Eye"; Dr. Joseph A. White, of Richmond, Va., discussed "Eye Troubles Attributable to Naso-Pharyngeal and Aural Disturbances."

**A Study of One Hundred and Fifty Cases of Disease of the Antrum of Highmore.**—Dr. L. C. Cline, of Indianapolis, presented this communication. Of the cases seen by him, six had sarcoma of the superior maxilla, and all the patients had stated that they had suffered with their teeth, thus leading him to believe that the long-continued irritation from an abscessed root discharging into the antrum had been a factor in the production of the sarcoma. The etiology of the cases of abscess was comprised under three divisions, viz., those due respectively to dental disease, those due to nasal disease, and those resulting from la grippe. All but twenty cases were chronic; seventy-five per cent. were on the right side. Ethmoiditis had been present in eleven cases. The speaker stated that he relied on peroxide of hydrogen for diagnosis. In his opinion, the best method of operating, and the one which secured the best drainage, was that through the alveolar process. When a tube was required he used silver wire twisted into the proper shape and size.

**The Relation of Nasal and Accessory Cavities and Dental Lesions.**—Dr. D. Braden Kyle, of Philadelphia, read a paper with this title. He stated that the abnormal and pathological conditions of the teeth causing nasal obstruction and disturbances might be considered under—(1) irregularities in the formation of the alveolar process, allowing the teeth to penetrate into the antral or nasal cavities, thus permitting the extension of the disease process, and (2) nasal or antral irregularities, with secondary lesions of the teeth. Mouth breathing contracted the arch, causing irregularity in the teeth and a characteristic droop to the nose. The period from birth to the time when osseous union occurred was the proper time in which to correct nasal irregularities and deformities. Thumb-sucking caused a characteristic alteration in the superior maxilla and floor of the nose. The irruption of the teeth into the antrum also showed an irregularity in development. Gases might form in the antrum from a diseased tooth. He regarded as suspicious a history of dental irritation in this region, with subsequent cessation of pain and later development of pressure symptoms in the cheek, with ozæna, the latter being either continuous or interrupted.

**The Determining Factors in the Symptomatology and Diagnosis of Infective Sinus Thrombosis.**—Dr. Fred. Whiting, of New York, read this paper. He dwelt at length upon the symptomatology, remarking that there was no need for apologizing for so doing, when only very recently the lack of familiarity with this very subject had led to the melancholy death of

one of the promising young surgeons of New York, without diagnosis and without operation. When a patient suffering with purulent otorrhœa complained of severe hemicrania in connection with sudden increase in the discharge, or recent diminution of the same, and simultaneously presented a degree of systemic disturbance not conformable with a tympanic or mastoid inflammation, we should be apprehensive of some form of infective intracranial invasion. If subsequently there were one or more chills, associated with high temperature and undue exhaustion, this suspicion should be converted into a positive conviction. The accession then of repeated chills of varying degree of intensity, from a sensation of chilliness only to a severe and protracted rigor, associated with rapid and excessive fluctuations of temperature, profuse and colliquative perspiration, rapid pulse and respiration, and great prostration, gave such a faithful portrayal of the salient features of infective sinus thrombosis that the existence of almost any of the local signs, if at all pronounced, would be accepted as absolute confirmation by even the most skeptical and exacting of medical attendants. The appearance of the local symptoms might be anticipated in their chronological order as follows: tenderness of the superior portion of the posterior cervical triangle, occipital œdema, neuroretinitis; tenderness along the course of the internal jugular vein, most marked and earliest elicited close beneath the angle of the jaw. In addition, there would usually be present œdema of the eyelids, turgescence of the external jugular vein of the opposite side, upon pressure, and a cord-like delineation of the internal jugular of the corresponding side, due to purulent phlebitis. The speaker expressed the belief that the percentage of mortality in sinus thrombosis was materially higher than the rate commonly attributed to it, for the reason that the temptation to suppress operative failures was of similar import and equal weight with the inducements to publish operative successes. To Zufal, above all others, was credit due for having initiated the steps which, with modifications as to detail only, were still followed in our attempts to relieve sinus thrombosis. It had been his prophetic utterance which had proclaimed the possibility of preserving life under conditions which had long been regarded as necessarily fatal.

**A Case of Brain and Metastatic Abscesses following Suppurative Otitis Media.**—Dr. Milton Greene, of Grand Rapids, reported this case, which had originated in a tonsillitis. Five weeks after a mastoid operation the brain abscess had been operated upon, by cutting through half an inch of brain tissue. Three ounces of fetid pus had been removed. The mediastinal and other abscesses had entirely healed before the brain abscess had been operated upon. There was a history of gonorrhœa, but no cocci were found. The man's improvement had been rapid, and his mind had become clear. Some weeks later a general cerebritis had caused his death.

**Four Cases of Otitic Cerebellar Abscess.**—Dr. B. Alexander Randall, of Philadelphia, reported these cases. In the first one an operation for mastoiditis had been followed by pleural empyema and death, and the autopsy had revealed an amazing destruction of both lungs and a cerebellar abscess the size of a pigeon's egg. Intact bone was present in all deeper directions about the mastoid. The second one was also a case in which a mastoiditis operation had been required. The back wall had been entirely lost, and the mastoid converted into one large cavity. The sigmoid sinus had been bare for one inch. Two square inches of the dura had been laid bare, and solid and apparently healthy bone reached. Two weeks later an abscess had formed at the clavicle. This had healed, but the woman's pulse had been 76 and her temperature 98° F. An operation for cerebellar abscess had been done, and during this, as a result of tearing the large mastoid emissary, there had been a profuse hemorrhage. She had died subsequently. In the third case a mastoid operation had been done, and subsequently an abscess cavity had been found in the cerebellum. This patient had recovered. In the fourth case a mastoid operation had been done. An exploratory operation had failed to reveal pus, but death had ensued, and the autopsy had revealed an abscess occupying nearly the entire right lobe. These cases were presented to illustrate the difficulties of diagnosis in cases of intracranial abscess, especially when located in the cerebellum.

**Fractured Base with Deafness, Tinnitus, Vertigo, Exophthalmos, Facial Paralysis, Mastoiditis; Operation and Recovery.**—Dr. J. A. Stucky, of Lexington, Ky., read the report of this case. After an injury the patient had been seen by him. There had been complete paralysis of the right side of the face, with the symptoms as stated in the title. A Stacke-Schwartze operation had been performed.

**Enzyme in the Treatment of Nasal Polypi; Angioma of the Nose and Chronic Otitis.**—Dr. T. R. Chambers, of Jersey City, read a paper with this title. The proteolytic enzyme which he had used in the treatment of the conditions stated in the title had been prepared by direct extraction from the peptic glands of the fresh pig's stomach, slightly acidulated. When diluted with an equal quantity of water it contained about the same percentage of hydrochloric acid as the normal gastric juice.

---

*Third Day—Thursday, June 8th.*

**Dangerous Complications of Acute Purulent Otitis Media.**—Dr. S. E. Allen, of Cincinnati, read this paper. He said that acute otitis media was caused by germ infection reaching the tympanic cavity by way of the Eustachian tube. The serious complications were due to a peculiar deep-seated germ activity. The general rule was, that cases whose symptoms were the most insignificant at first were the ones that gave rise to the greatest trouble eventually.

**Hypertrophy of the Turbinated Bodies, and Their Relation to Naso-Pharyngeal and Middle-Ear Inflammations; with Deductions Based upon Fifteen Hundred Operations.**—Dr. Christian R. Holmes, of Cincinnati, read a paper with this title, and illustrated it by microscopic slides and the use of the projection microscope. Instead of uncapping the middle turbinate, the author removed the entire bone and covering with especially devised scissors. The inferior turbinate was sawed into with a very narrow saw. The first incision was from below upward, and then from within outward. Where the tissue was redundant the dependent portion was removed after the saw had been withdrawn. The object was to produce a bony cicatrix. The instruments were shown, and the manner of operating illustrated on the cadaver. The writer's results had always been satisfactory. Cocaine anæsthesia and absolute rest were sufficient to prevent hemorrhage.

**The Anatomical Variations of the Nasal Chamber and Associated Parts.**—Dr. M. H. Cryer, of Philadelphia, read this paper. He said that variations were so common that it could not be exactly said which constituted the typical normal anatomy and which the variations. Occupation would modify the general shape and character of the face and head, especially in youth. Climate and its consequent environment had an influence on the shape of the head. One side of the head was generally found to be different from the other. The paper was illustrated by

stereopticon views, and many slides were presented showing that many skulls had five meatuses, although it had been hitherto stated that there were but four.

**Headaches of Nasal Origin.**—Dr. Carolus M. Cobb, of Lynn, read this paper. The speaker briefly alluded to some intranasal affections that caused headaches, and concluded that an examination of a patient suffering from headache was not complete unless the condition of the nasal cavities has been inquired into. He had used for some time a method suggested by Dr. H. B. Chandler, of Boston, to determine whether or not asthenopic symptoms were due to nasal disease. The diagnosis was made by watching the action of the pupil while under the influence of concentrated light. If the pupil contracted quickly when illuminated in this way and as quickly dilated again, the asthenopia was caused by intranasal disease. The intranasal diseases which were associated with this pupillary reaction were almost invariably an inflammatory condition of the middle turbinate body, and chronic rhinitis, which was produced by systemic conditions, such as uricacidæmia and some other forms of auto-intoxication. The asthenopia might be exaggerated by the nasal disease even when errors of refraction existed.

**Sarcoma of the Nasal Passages.**—Dr. H. V. Wurdeman, of Milwaukee, read this paper. He presented a brief report of a case in which numerous growths had been removed and their bases cauterized. These had been examined and shown to be small round-celled sarcoma. There had been no recurrence since 1891. Aside from the pathological interest of this case, the fact of permanent recovery from nasal sarcoma was of considerable import, showing that these cases might sometimes be cured if radical removal of the growths was done sufficiently early.

**Adeno-Sarcoma of the Nasal Septum.**—Dr. A. R. Baker, of Cleveland, read a paper with this title. The first tumor had been, and had been alleged to be, benign, while the second one had been malignant. Rouge's operation had been performed, and there had been no recurrence in fourteen months.

**The Treatment of Naso-Pharyngeal Adenoids.**—Dr. Louis J. Lautenbach, of Philadelphia, read a paper on this subject. He used his own or the steel finger-nail to remove the growths. This procedure was repeated two days thereafter; then every three or four days until the patient was well. Ether he considered too dangerous, and the treatment following ether he looked upon as inhuman.

His views were combated by Drs. Theisen, Quinlan, and Mayer, the latter stating that he never used the finger-nail, even for diagnosis.

**Report of a Case of Echinococcus Cyst of the Nose.**—Dr. W. K. Rogers, of Columbus, reported this case.

**Specimens Demonstrating the Accessory Cavities, and Their Relation to the Nasopharyngeal Passages.**—Dr. Christian R. Holmes, of Cincinnati, exhibited these specimens.

**Officers Elected.**—*Chairman*, Dr. Christian R. Holmes, of Cincinnati; *Secretary*, Dr. J. A. Stucky, of Lexington, Ky.

**Hot Sand in Therapeutics.**—The chief indications for the employment of these baths are: To diminish dropsical conditions, whether dependent on heart, liver, or kidneys; in the absorption of pleural exudates; in the treatment of chronic arthritic troubles, especially arthritis chronica deformans, in which the severe pains are greatly lessened, frequently the exudates are so far removed that the mobility of the joints may be greatly increased. Excellent results have been obtained in sciatica as well as in acute and chronic articular rheumatism.—Grawitz.

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

GREAT HOSPITAL BAZAAR—COLLEGE CHARTER—KALA-AZAR—PROGNOSIS OF PERICARDITIS—PROFESSOR OSLER—PATHOLOGY—ROYAL SOCIETY—MOSQUITOES—MIDWIVES BILL—SUNDAY FUND—SMALLPOX—CANCER SOCIETY—PROFESSOR SCHAFER—DUBLIN CHARITIES—DR. FREDERICK J. SMITH ON DIAGNOSIS—THE LATE MR. TAIT'S ASHES.

London, June 23, 1899.

The event of the week has been a splendid bazaar on behalf of the Charing Cross Hospital, held at the Albert Hall, which was fitted up for the occasion regardless of cost. All the aristocracy and plutocracy seem to have combined to make this the most notable function of the fashionable season. The stalls were fitted up to represent various nationalities and their characteristic products. Some of the things brought over from various countries have never been on sale here before, and some perhaps never before seen here. Need I say that one of the finest stalls was the American? It was also one of the most popular. There was also an American bar, at which a great deal of money was spent on fluids with peculiar names, and on the nature of which no questions were asked. A *café chantant* was carried on at this point, after five P.M. Mrs. MacKay, Mrs. Brown-Potter, and Lord Yarmouth were largely responsible for the American arrangements, and to their efforts much of the success was due. A souvenir, edited by Mr. Beerbohm Tree, and to which a wonderful array of literary and artistic celebrities contributed, will add largely to the proceeds. If society must be thus amused and excited, it is well that the profits of the entertainment should go to the support of our hospitals.

The Society of Members of the College of Surgeons is making an appeal for justice at the hands of the Council, on the occasion of the application for an additional charter in celebration of the college centenary. As I have several times remarked, the thousands of members have no part nor lot in the management of their college. Yet the Council is in reality trustee for the members, in whom the property was vested by the original charter of 1800. The fellows, who number 1,195 against 17,199 members, elect the Council. The members have long asked that they should elect a certain number of councillors, but jealousy has prevented the least modicum of justice. It is suggested that it would be a gracious act on the part of the Council to embody some compliance with the members' wishes in the new charter they propose to apply for. I scarcely expect that this appeal will be complied with. A more effectual method would perhaps be for the members to oppose by every legal method the issue of a new charter, which did not recognize their right to representation in the governing body of their own college.

There were two papers at the last meeting of the Medico-Chirurgical Society, but neither of them excited any discussion. The first was by Dr. Leonard Rogers on kala-azar, the epidemic fever of Assam. Dr. Rogers submitted a paper on this subject last year, in which he maintained that the disease is really a severe malarial fever which after a succession of unhealthy seasons has attained a certain degree of communicability. In accordance with this view Dr. Rogers made the following recommendations, which were carried out with considerable success: (1) Newly imported coolies to be placed in fresh lines and not allowed to communicate with old infected ones; (2)

in slightly infected lines all infected persons with their households to be moved into separate segregation lines and the huts they have used to be burnt; (3) in badly infected lines all the healthy to be moved during the dry, cold-weather months when infection is at the lowest, and placed in new lines, infected persons and their households to be segregated and the infected line abandoned. These measures have been adopted in various infected tea-gardens in Assam, and the disease, which was formerly fatal in seventy to ninety per cent. of those attacked, is now regarded as controllable.

The other paper was on "The Remote Prognosis of Pericarditis," by Dr. J. H. Sequeira, and was founded on the recent work of Barnard and Leonard Hill, which showed that the pericardium is a support to the heart during muscular exertion. From this Dr. Sequeira suggested that the remote prognosis required reconsideration, as a softened, dilated pericardium would cease to give the support and the heart might dilate and fail. On the other hand, if the pericardium became dilated and adherent to the chest wall it would lead to failure of compensation, but if the sac was not dilated adhesions would be of little importance. Dr. Sequeira had traced the after-history of one hundred and thirty cases of acute pericarditis, one hundred of which he had personally examined, many at frequent intervals. They support his conclusion that the amount of dilatation of the pericardium affects the remote prognosis of acute pericarditis, and that whatever augments the labor of a heart working in a dilated pericardium tends to impair the power of compensation.

Professor Osler has been here and delivered the Cavendish lecture for the West London Medico-Chirurgical Society. He took for his subject "Cerebro-Spinal Meningitis," and more than two hundred were assembled to hear him. Dr. Halsted was also over here and present at the lecture of his colleague. The disease is rather rare here, and as the professor has seen a fair share of it in Baltimore, you may judge that he was listened to with an interest in his clinical experience as well as for the sake of his position and personality. After the lecture there was a conversazione. Music, smoking, and light refreshments were not wanting, and a very long evening was generally declared to be as successful as it was interesting.

Oxford is likely to have a first-class pathological laboratory at an early date. An anonymous donor has offered £5,000 toward the expense, provided the matter is taken up at once. The buildings required will cost about double, and the first steps toward providing the necessary funds have been passed, and it is expected that little if any opposition will be offered in the other stages.

Birmingham, also, is promoting pathological study. A new laboratory is being built in connection with Mason College, and Dr. R. F. C. Leith, of Edinburgh, has been elected to the professorship.

The "ladies' night" at the Royal Society naturally attracts a brilliant assemblage, and the conversazione on Wednesday was as successful as could be desired. The exhibits were extremely interesting. Among them was Davidson's apparatus for showing Roentgen-ray pictures in stereoscopic relief. Dr. Manson showed malarial parasites, and near his preparations was a collection of mosquitoes lately arrived at the Natural History Museum. Pathogenic bacteria and many other objects were also on show.

The Liverpool School of Tropical Medicine is sending an expedition to Sierra Leone under the leadership of Major Ronald Ross, to study the mosquito in relation to malaria.

Exit the midwives bill, and we shall at least be delivered from its obnoxious shadow for another year at least.

The amounts reported as received by the Hospital Sunday Fund up to yesterday exceeded £35,000.

A death from smallpox has been reported, the first during the half-year. Last year there was only one death from this disease in London. And yet there are antivaccination maniacs among us!

A cancer society has been established to promote the increase of knowledge respecting this disease, to found a special research library, and to urge a parliamentary inquiry. The last object is not likely to succeed in a hurry, and perhaps the promoters had better direct their first efforts to the establishment of the laboratory.

Professor Schafer, F.R.S., succeeds to the late Professor Rutherford's chair in the University of Edinburgh.

Dublin charities benefit to the amount of about £100,000 under the will of the late James Weir.

Dr. Frederick J. Smith, of the London Hospital, will shortly produce a work on diagnosis.

The remains of the late Mr. Lawson Tait were cremated and the ashes placed in the Gogarth Cave in accordance with his wish.

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 8, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 98 | 140 |
| Typhoid fever | 16 | 10 |
| Scarlet fever | 125 | 7 |
| Measles | 216 | 13 |
| Diphtheria | 191 | 42 |
| Laryngeal diphtheria (croup) | 10 | 6 |
| Cerebro-spinal meningitis | 0 | 4 |
| Chicken-pox | 12 | 0 |
| Smallpox | 3 | 1 |

**Blood-Letting.**—Among the Ashburnham manuscripts which will shortly be brought under the hammer in London is a collection of medical tracts in verse and prose, recipes, etc., of the fourteenth and sixteenth centuries, containing some extremely curious things. A treatise on blood-letting commences thus:

> "Maystris that vithyth blode letying
> And that wyth geteth your levying
> Here ye may lere wysdom ful gode
> In what place ye schulle let blode."

—*London Times.*

**The Evil of Continued Mental Anxiety.**—Some years ago I collected the statistics regarding the lives of stockbrokers in a certain city, and was surprised to find that nearly every person who lived a sober life and continuously studied the ups and downs of the money market failed either mentally or physically in a short time—less than a dozen years—ultimately disappearing from active life. On the other hand, the men who were operators of great skill and coolness, and who lived regularly most of the time, but occasionally gave way to the drink habit and disappeared several days at a time on account of helpless drunkenness, lived longer and had fewer mental disorders. This, of course, cannot be construed into an argument in favor of drinking even occasionally, but was to my mind a very strong indication of the benefit coming from the occasional complete relaxation from intense mental anxiety. Frequent vacations passed in the

woods, or at the seaside, without social duties, and where temporarily men could resort as nearly as possible to primitive life, even for short periods, would, I am convinced, be much better Protracted anxiety without rest breaks more men than does hard intellectual effort.—"System of Practical Medicine," vol. iv., p. 784.

**Birth Rate in Europe.**—Signor Bodis, a well-known Italian statistician, has published tables showing the order in which the countries of Europe are classed in decreasing series according to their mean birth rate: 1, Russia in Europe; 2, Hungary; 3, Servia; 4, Roumania; 5, Austria; 6, German Empire; 7, Italy; 8, Spain; 9, Finland; 10, Portugal; 11, Holland; 12, England and Wales; 13, Scotland; 14, Denmark; 15, Norway; 16, Belgium; 17, Sweden; 18, Switzerland; 19, Greece; 20, France; 21, Ireland. It will thus be observed that Russia has the largest percentages of births and France and Ireland have the smallest.

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ending July 8, 1899:

SMALLPOX—UNITED STATES.

| | | Cases. | Deaths. |
|---|---|---|---|
| Georgia, Savannah | June 18th | 5 | |
| Illinois, Chicago | June 24th to 30th | 2 | |
| Indiana, Evansville | June 24th to July 1st | 6 | |

On Japanese steamship *Nippon Maru*, from Hong Kong and Japanese ports, for San Francisco, May 26th, 1 death.

**Purulent Otitis Media.**—When the tympanic cavity has become the seat of chronic suppuration, with ulceration of the mucous membrane extending into the antrum and mastoid cells, it becomes a standing menace to the safety of the patient. The disease progresses insidiously, and one cannot be certain as to where or when it may end. A person might as well have a charge of dynamite in the mastoid antrum or cells, as one cannot know the moment when accidental circumstances may arise which may cause the infective matter to become widely disseminated all over the cerebro-spinal system. Chronic otorrhea is much too lightly regarded, and is frequently considered as a mere inconvenience instead of a menace to life.—MACEWEN.

**Cremation Increasing.**—According to statements made at a recent meeting of the Cremation Society, Sir Henry Thompson presiding, there would appear to be a steady and marked advance in this method of disposal of the dead. From the following figures the progress made at Woking alone may be seen: 1885, 3 cremations; 1886, 10; 1887, 13; 1888, 28; 1889, 46; 1890, 54; 1891, 99; 1892, 104; 1893, 101; 1894, 125; 1895, 150; 1896, 137; 1897, 173; 1898, 240. The cost still remains prohibitive, being, it is believed, from $50 to $75 at Woking. A number of towns are applying for power to erect crematoria, and the movement seems well under way.—*Medical Magazine.*

## Books Received.

*While the* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE TWELVE TISSUE REMEDIES OF SCHUSSLER. By Dr. W. Boericke and Dr. W. A. Dewey. Fourth edition. 8vo, 424 pages. Boericke & Tafel, Philadelphia.

A MANUAL OF SURGICAL TREATMENT. By W. W. Cheyne, M.B., and Dr. F. F. Burghard. Vol. I. Royal 8vo, 285 pages. Illustrated. Lea Brothers & Co., Philadelphia.

PROGRESSIVE MEDICINE. Edited by Dr. H. A. Hare. Vol. II. Royal 8vo, 468 pages. Illustrated. Lea Brothers & Co., Philadelphia.

FRACTURES AND DISLOCATIONS. By Dr. H. Helferich. Translated from the third edition by J. Hutchinson, Jr., F.R.C.S. 8vo, 130 pages. William Wood & Co., New York. Price, $3.00, net.

CLASS BOOK OF PRACTICAL PHYSIOLOGY. By Dr. De Burgh Birch. 12mo, 273 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia. Price, $1.75.

HAY-FEVER AND ITS SUCCESSFUL TREATMENT. By Dr. W. C. Hollopeter. Second edition. 12mo, 151 pages. P. Blakiston's Son & Co., Philadelphia. Price, $1.00.

SHALL WE DRINK WINE? By Dr. John Madden. 8vo, 220 pages. Published by the author.

### LIQUID AIR; ITS APPLICATION IN MEDICINE AND SURGERY.[1]

BY A. CAMPBELL WHITE, M.D.,

NEW YORK.

LIQUID air is a substance which is to-day attracting the attention and interest of scientists all over the world. The subject occupies in the scientific and popular journals the space and attention only a short time ago devoted to the wonders of electricity. As the study of the toxins and antitoxins hold our attention to-day in medicine, giving to us such promise of success in the treatment of those diseases over which heretofore we have had so little control, so in the scientific world Prof. Charles E. Tripler seems, in the making of liquid air in large quantities and at small expense, to have solved a problem which opens up a new field destined possibly to revolutionize motive power and refrigerative processes. Has Professor Tripler also opened up a new field in medicine or given to us a therapeutic measure of any appreciable value?

For some years past Professor Tripler has urged with considerable persistency that such is the case, and that we have no right to judge of the efficacy of liquid air from the results we have obtained by the use of cold as heretofore employed in therapeutics. "The cold you doctors have made use of," he says, "is hot compared with air at 312° F. below zero."

Here and there during the past year or two liquid air supplied by Professor Tripler has been used by different physicians on several manifestations of disease, more particularly carcinomata. The result has been glowing accounts of its power to abort and cure even malignant disease.

Some months ago I determined to give liquid air a fair and systematic trial, and was generously assisted in doing so by Dr. Thurston G. Lusk and his associates at the Roosevelt out-patient department and by Prof. George M. Fox and his assistants at the Vanderbilt clinic. Professor Tripler has willingly supplied us twice a week with all the liquid air we could use. He has always had it ready for us at the time appointed, so that our course of treatment has not been spasmodic, but pursued regularly every three days when indicated.

As to the cost of liquid air made by the Tripler process, a gallon does not cost anywhere near so much as a gallon of mineral water retails for on the market to-day. Its temperature is 312° F. below zero. It contains nitrogen and oxygen, with a variable quantity of carbon dioxide. The proportion of nitrogen and oxygen is about three parts of the former to one of the latter by weight and about four to one by measure. It contains no hydrogen, as hydrogen is not liquefied at the temperature of liquid air. It is a somewhat opal-colored fluid, and when filtered (as it can be by use of ordinary filter paper) it resembles in color the atmosphere as seen in the distance on a clear day. Viewed in any ordinary receptacle, the fluid is boiling, giving off a white vapor which rapidly disappears, the vapor falling toward the ground because it is so cold; the hand can be put into the liquid without injury, if it is immediately withdrawn. The liquid feels dry and cold and leaves no moisture on the hand. When applied to the hand, on account of its extreme coldness, it gives a sensation of burning or tingling, similar to that experienced when the faradic current is applied. When a cup of liquid air is thrown upon the floor it behaves just as a cup of water would do if thrown on a very hot stove; it makes the same explosive noise and rapidly disappears in vapor, leaving no moisture or evidence behind. The floor, of course, or any article in the room, is some 400° F. hotter than the liquid air. Liquid air is not an explosive unless hermetically sealed. It can be put in a bottle or ordinary milk can providing there is a small hole in the stopper or cover. When put into such a receptacle it boils very rapidly until the temperature of the bottle or can has been reduced, so that it is covered thickly with frost and so cold that it could not be touched with the hand without causing frostbite.

If a lighted match is dropped into the liquid immediately after the latter has been poured into a glass, the light will be extinguished. Nitrogen evaporates much more quickly than oxygen, so that after a short time the liquid becomes very rich in oxygen, and if a lighted match should then be dropped into it, it would burn brilliantly, and combustion would be perfect; a lighted cigarette would blaze and be completely burned if dropped into it; even steel is melted in the same way if brought to a white heat before exposing it to the liquid.

Liquid air will transform any liquid or ether to the solid state. It will freeze alcohol solid, when the alcohol will explode violently if ignited.

Professor Tripler fills a tin dipper with liquid air and after a minute or two picks up the dipper and crushes it into many fragments between his hands. Absorbent cotton soaked in liquid air and ignited acts like gun-cotton; this is due to the cotton being so rich in oxygen. Liquid air is transported in a can within a larger can, the intervening space being filled in with hair felt.

Heat destroys all forms of germ life at a temperature of 160° F. Up to this time we have been unable to tell the effect such extreme cold would have on the bacteria. Through the courtesy of Dr. William T. Jenkins, commissioner of health, the privileges of the hospital laboratory of the department of health were given to me to test the effects of liquid air on germ life, and with Dr. Parks' assistance we tested the effects on typhoid, anthrax, and diphtheria bacilli. In order first to test

[1] Experiments with liquid air seem to be universally fascinating, and many of them are equally dangerous; so for this reason Professor Tripler is not inclined, for the present at least, to assume the responsibility of furnishing liquid air promiscuously to the profession. It is quite possible in the near future that a place will be arranged with all the facilities for the administration of liquid air, so that physicians can take their patients to it as they would to a private hospital, and conveniently apply the treatment. I intend to continue the use of liquid air throughout the summer at Dr. Fox's clinic, where any physician who has some dispensary patient, upon whom he would like to have the liquid air tried, can take him for treatment.

the effect of extreme cold on these germs without bringing them in direct contact with the liquid, we put into a number of capillary tubes pure cultures of virulent anthrax, diphtheria, and typhoid bacilli. These capillary tubes were marked for identification, sealed at both ends, and dropped into a glass of liquid air. The liquid was renewed at intervals, so that the tubes were at all times completely submerged. Some were removed in thirty minutes, others in forty-five minutes, sixty minutes, and ninety minutes. After they were removed from the liquid and the sealed ends were broken, they were dropped into separate culture tubes containing fresh sterilized bouillon, and these in turn marked for identification. These bouillon tubes were placed in incubators kept at a temperature of 38° C., where they remained for over forty-eight hours, when they were all examined and found to contain pure cultures of anthrax, typhoid, and diphtheria bacilli according as they had been inoculated. In order to test whether liquid air itself in addition to its temperature would have any effect on germ life, a culture medium containing numerous colonies of anthrax bacilli was dropped into a glass of liquid air and allowed to remain over an hour. When removed, a fresh sterile culture medium was inoculated with the one exposed to liquid air and placed in the incubator as before. The same result was obtained as when the capillary tubes were exposed.

Dr. J. H. Huddleston tried the effect of liquid air on vaccine virus, and found that fifteen minutes' or less exposure to the liquid air had no effect whatever on the power of the virus to produce vaccination. Longer exposures to liquid air are now being tried.

About three-quarters of the ear of a rabbit was completely frozen by placing it in liquid air for some minutes. The ear was frozen so stiff that a small piece of the tip was broken off with the fingers without pain or hemorrhage. In less than ten minutes' time the circulation was entirely re-established with hemorrhage at the point where the piece had been broken off; the frozen part had regained its normal temperature (possibly a little higher) and color. The ear remained perfectly normal for about five days, when it began to swell somewhat, and by the end of two weeks about one-half of the frozen part had shrivelled and dropped off. The remainder of the ear regained its normal condition.

In applying the liquid air to the tissues of the human body, I have used it in the form of a spray and by means of a swab dipped into the fluid. If a spray of liquid air is applied to the skin, the part to which it is applied at once becomes anæmic and perfectly white or colorless. If the spray is applied for only a few seconds, the color as quickly comes back, and the skin is congested for some minutes afterward. Within much less than a minute's time, by means of the spray the part is frozen as hard as ice; but even if it is frozen as hard as this, the circulation returns in a few minutes without any injury to the tissues, providing the part is not the end of some extremity, such as the finger tip, in which case I would fear loss of tissue, as in the case of the rabbit's ear. There is no pain in the application, excepting at the very beginning, when there is a slight burning or tingling. It also completely anæsthetizes the part to which it is applied, without freezing it solid. I have tried the liquid air in a number of cases as a local anæsthetic with invariable success; and another important advantage it has here is the absence of hemorrhage during the operation, enabling the operator to apply the dressing before any hemorrhage sets in, the dressing then being sufficient to stop any oozing. An infected bursitis over the olecranon was anæsthetized, incised, cleaned out thoroughly, and dressed without pain or hemorrhage. When the dressing was removed, some days afterward, the edges of the wound were found clean and the cavity itself was free from pus. The repair was more rapid if anything than would naturally have been expected. Another case was that of a boy who had a blank-cartridge wound in the palm of his hand. The boy was extremely nervous, but it was deemed necessary to make an incision and examine for a foreign body. The liquid air was applied too freely in this case, so that when an incision was attempted it was found that it was as impossible to incise the hand with the scalpel as it would have been to cut a cake of ice. After waiting about thirty seconds the operation was satisfactorily performed without pain or hemorrhage and with no further application of liquid air. When the boy returned in a few days, the wound was in a perfect condition, there being no loss of tissue, and he continued to do well until recovery. In using liquid air as a local anæsthetic I believe it better to apply it intermittently while the operator is working than to try to freeze the part so that it will remain senseless for any length of time. This intermittent use of the spray would not be necessary when a simple incision was required, as in the case of opening an abscess.

I first began the use of liquid air in the local treatment of ulcers of the leg, chiefly varicose, many chancroids, and some specific ulcers. So many of these cases have now been treated with liquid air, that it can be said with positiveness that we have nothing at our disposal to-day which will so quickly, thoroughly, and with as little pain clear up the edges and stimulate the surface of an ulcer to granulations as liquid air does when properly applied. The application should not be made so frequently as to break down the new granulations as they form. After the first two applications to a varicose ulcer, one application a week is usually sufficient. To a chancroid or mixed sore, one application pretty generously applied is sufficient. A "beefsteak" chancre requires two or three applications, three or four days apart. All ulcerations treated with liquid air seem to do better when followed by a dry dressing, such as aristol, subgallate of bismuth, or stearate of zinc, instead of any unguent.

An abscess, boil, carbuncle, or bubo in the early stage is aborted absolutely with one thorough freezing. If it is more advanced, several applications at intervals of twenty-four hours are necessary. Whenever pus has formed in large quantity it is advisable to anæsthetize with liquid air, incise, and evacuate. In cases of bubo and carbuncle well advanced, it is unnecessary to curette if the liquid air is applied generously to the base of the abscess after incision. In all these cases the pain is instantly relieved after the application of liquid air. No sloughing follows excepting in the case of fairly well-advanced carbuncles and in some of the abscesses when the overlying skin has become devitalized from tension and inflammation. In these cases the slough is only superficial, and the ulcer left readily heals.

In a number of cases of sciatica and of herpes zoster, one case of intercostal neuralgia, and one of facial neuralgia, liquid air has been tried. In every one of these cases instant and, so far as we are able to judge at the present time, permanent relief has been obtained by applying the liquid to the spinal end of the affected nerve. In one case of sciatica the air was applied to several points in the course of the nerve. In two cases of herpes zoster (all were situated on the chest wall) the eruption had completely dried up three days after application, and in the other cases about five days was required. In none of these nerve cases was the air applied more than once, and in no case was the application severe enough to cause blistering or sloughing.

Two cases of facial erysipelas were treated, not with a spray or swab, on account of the extent of surface involved, but by rolling a glass bulb filled with liquid air over the tissues involved. The surface temperature, the inflammation, and pain subsided at once; but it was impossible to get any subsequent history of the cases, so that the result of the single treatment is doubtful.[1] I should imagine it would require a number of applications at intervals of several hours to accomplish much good in erysipelas.

An interesting experiment was performed on a case of ivy poisoning involving the entire left forearm and hand. A band around the forearm about three inches wide was slightly frozen with the spray; then the usual treatment was applied to the entire poisoned area, including that part which had been treated with the air. At the next dressing the band was very distinct, and it was well marked only from the fact that the part frozen had improved so much more than the remainder of the forearm and hand, the inflammatory process having subsided. The liquid air was tried on several cases of ringworm with negative results.

The prospects of the use of liquid air in the treatment of lupus is extremely encouraging. One case of lupus erythematosus, involving the frontal region, both ears, and one side of the face, was put under treatment about two months ago. After two treatments the affected areas entirely desquamated, leaving the derma in perfectly healthy condition, slightly red, and no eschar. This was an obstinate case which had been under treatment for a long time, resisting everything that had been done for it. There is no evidence of any tendency to recurrence, and we have every reason to believe the case has resulted in a cure. Two other cases of the same disease, but involving a large area, are under treatment now (only limited areas being treated at a time), and there is evidence in these that the result will be fully as salutary.

As to the treatment of carcinoma with liquid air, I cannot express any positive opinion, on account of lack of experience. I have several cases under the treatment now, and although it is but a short time now since treatment was begun, I am quite hopeful as to the ultimate result. Several cases of epithelioma have been treated with liquid air during the past year by different physicians in and about New York. The result has been glowing accounts of the positive cures which have followed its use in this class of cases. I regret to say that I am unable to confirm or deny these claims, excepting in one instance in which I have strong evidence that an epithelioma of the nose has to all appearances been cured. Of course too short a time has elapsed to exclude any recurrence of the disease, but, even though the tumor should reappear, there is no reason to believe it would not respond to the treatment as readily as in the first instance.

The question is undoubtedly raised at once, Why should liquid air have any effect on carcinomatous tissue, or why should it have any effect other than ordinary extreme cold, in any of the cases previously mentioned in this paper? In answering this question, we must constantly keep in mind the nature of the fluid we are using. It is air, and only differs from ordinary air, that we breathe and live in all the time, in that it is cold. To be sure, it is in the liquid state and obeys all the laws of the fluids, but it is not wet or moist in exactly the same sense that water or other liquid is. Therefore, when we apply liquid air to a part of the body we are bringing into contact with that part pure cold, and nothing else which is not already natural to it. For example, if you apply the liquid air to the skin on which there is a drop of water or perspiration, a blister will result with loss of tissue following; if you picked up a glass which had just contained liquid air, the temperature of which had been reduced to something below 200° F., a greater destruction of tissue will result than if liquid air had been applied to the part for a much longer time than when the fingers were in contact with the glass.

In another part of this article, I mentioned that there were two ways of applying the liquid air—viz., by the spray and by the swab. In all the cases heretofore mentioned the spray has been used, because they were a class of cases in which no loss of tissue was desirable; but when it is desired to remove some tissue, such as a nævus or wart, recognizing and illustrative of the point I have just made, we use the cotton swab dipped in the air and apply it to the part we wish to destroy, and it is needless to say that the desired result is obtained.

All authorities, in speaking of the local influence of cold on the tissues, emphasize the fact that it is long exposure to wet at low temperature, rather than dry cold, which produces frostbite.

I noticed in a recent issue of *The Scientific American*,[1] in an article on "Liquid Air," the following statement: "The suggested employment of liquid air as a caustic in surgical operations is a good example of the absurdities proposed by dishonesty or ignorance in order to impress the public. Even such mild cooling agents as the ether spray have to be used with great care, since there is much danger of causing mortification beyond the tissues intended to be acted upon." The author could have given his subject but little thought, or his experience in the effect of cold on the tissues must have been extremely limited. Of course when we apply the ether spray we do not want mortification to follow even in those parts intended to be acted upon, and experience shows that that is not a result. In one of our old English text-books I find the best answer to this sweeping statement. Erichsen, in describing frostbite, says: "Experience teaches us that the tissues (healthy) may be completely frozen and kept in that state for a minute or more without suffering any injury." Is it not reasonable, considering the pathology of carcinomatous tissue, to suppose that the repeated applications of liquid air to these tumors will arrest the rapid and lawless cell multiplication which is the manner of their growth, and effect a recovery providing no metastasis takes place?

Remembering that there is a difference in temperature between the liquid air at 312° F. below zero, and the human body at 98.6° F. above zero, of over 400° of temperature, it can readily be seen that from no other means that we have to employ could we produce so sudden and extreme a shock to a localized part of the body, without localized destruction of tissues or without some effect on the general system. It takes only a second or two to produce locally the most extreme cold, and but a little more than that time for the part to regain its temperature; thus, by repeating the operation several times at short intervals, great stimulation, which is purely local, is obtained. The involuntary fibres contract, and the blood-vessels contract undoubtedly to the last degree, only to dilate as quickly on the removal of the spray.

The experiments at the laboratory have demonstrated, beyond almost all doubt, that liquid air is not an antiseptic, and that germs can resist a temperature of 312° F. below zero, even though exposed to it for a long time. Further experiments will be made to determine whether there is a limit to the length of

[1] Since writing this article I have seen one of the patients referred to. I find that after making the application as described there was no further pain, and the swelling and inflammation entirely subsided within twenty-four hours. Possibly the same result obtained in the other case, and for that reason the patient did not return

[1] Scientific American Supplement, No. 1,226, July 1, 1899.

exposure they can withstand, and Professor Tripler in a short time purposes to try a more extreme cold or still a lower temperature on germ life, by exposing the bacilli to liquid hydrogen. Knowing that cold inhibits the activity of bacteria for a time, it is more than likely that this result is obtained when the liquid is applied to a local infection, and if the application is repeated with some frequency it will be of great assistance to the body in overcoming their activity, and in this way will really serve the purpose of an antiseptic.

When we consider what liquid air is, and how it acts on the tissues, I believe it will not be difficult to understand why our results have been so universally satisfactory in those cases in which it has been used, and I think there is reason to hope that we have in liquid air a thereapeutic agent which will remove many otherwise obstinate superficial lesions of the body, and cure some lesions which have heretofore resisted all measures of treatment at our disposal, including the knife. I am firmly convinced, with the experience already had with its use, that it is a specific in the treatment of such neurotic lesions as herpes zoster, sciatica, and intercostal and facial neuralgia, affording instant and continued relief after one application over the spinal end of the affected nerve.

The use of liquid air in medicine, *i.e.*, in the pulmonary diseases, in the reduction of fever, etc., opens a large field, one which presents many obstacles at the very start, and possibly much hope for the future. This branch of its usefulness has received no little thought, but thus far slight progress has been made in this direction.

If further use of liquid air continues to demonstrate that it is to be of service to the practitioner, I shall endeavor to present the subject in the fall to one of the societies, when greater experience, a practical demonstration of the method of its use, and a presentation of cases under treatment will bring more forcibly and conclusively the subject of liquid air and its application in medicine and surgery to the attention of the profession.

## SHOCK IN MODERN SURGERY.[1]

By GEORGE F. SHRADY, M.D.,

NEW YORK.

While reading an interesting and practical paper, presented some time ago before this society by Dr. McBurney, on the unnecessarily large mortality after surgical operations, it occurred to me that still another element than that of time selection for such procedures was worthy of grave consideration. Much as we should like to believe to the contrary, a great deal of the mortality rate after operative work is due to surgical shock which might possibly in many cases be prevented. We all know that in a certain percentage of cases this melancholy result is inevitable as being the last and only chance in a desperate venture. The determination on the part of the surgeon to do and dare when the odds are against him is an evidence of the highest order of courage, and should be applauded accordingly. It is not to such instances that any criticism should be directed, but rather to those in which, to a certain degree at least, the outcome is under the immediate control of the surgeon or his assistants. Strangely as it may sound in this day of brilliant surgical triumphs, when nothing, however venturesome, in surgical technique is beyond the sphere of realized demonstration, we are nevertheless inclined to forget some of those fundamental principles in operative work which meant so much to those who have preceded us, long before anæsthesia offered its opportunities or asepsis became the *sine qua non* of our present possibilities. Then it was that everything bent to speed and dispatch in wielding the knife, and the shortest time employed in so doing meant the highest evidence of skill. Now it would appear that with the present immunity from pain on the part of the patient, and the insurance against wound infection on the part of the surgeon, we are swinging to the other extreme of wasting time and prolonging shock by methods which can hardly commend themselves to the careful and conscientious operator. The question as to whether or not the patient is able to survive a long operation has often more to do with the actual time of the ordeal than with any thoroughness which may be brought to bear on its performance. While the thoughtful operator is always weighing such chances in his own mind, the inexperienced worker is easily tempted to trust too much to the staying powers of his subject. The account is then squared by the simple statement that the patient was unable to survive the shock. From the standpoint of inducing shock in most of our modern operations I am quite convinced that the period of etherization is often too much prolonged; that there is too much deliberation in the elaboration of unnecessary details of manipulative manœuvres—the interest in the operation offsetting that in the patient—and, lastly, that the needless elaboration of our present methods of dressing the wounds has frequently a great deal to do with the ultimately prostrated condition of the patient. Much has been written on the subject of anæsthetics in operations, their methods of administration, and their relative merits regarding safety, but there appears in many quarters a strange indifference to the reasonable curtailment of time that the patient should be under their continuous influence. The comparatively few accidents that are directly charged to either of them are so apt to quiet our fears regarding their ultimate effects, especially those connected with increased shock, that the mere period of anæsthesia and the quantity of drug given are generally considered of very small moment.

By many it is believed that any additional shock is impossible so long as the mere pain of an operation is abolished. We must not forget, however, that shock is a composite condition, a jar to the equilibrium of the entire sympathetic system, of which mere pain is oftentimes an insignificant part. It is the extra and peripheral irritation of which the patient is unconscious which is a more or less constantly working factor in determining the retro-active influences of exhausted nervous centres. The insidious influence of this complex condition is too apt to be overlooked in striking the balance of chances for the patient. The question of actual and oftentimes permanent injury is eliminated in proportion to the time he is subjected to such influences. With ether and chloroform we may be satisfied that we save the patient from positive agony, but we are constantly wasting his nervous force of resistance the longer we imagine we secure him against obvious injury. We must not forget that the prolonged administration of an anæsthetic is, independently of the operation, a means of shock in itself. While ether may tend at first to modify shock, its prolonged use adds to the depression of the patient. The same may be said for chloroform. The bodily temperature is lowered if the administration of either continues longer than an hour or hour and a half. Often, especially in chloroform cases, the normal temperature is not restored until the lapse of twenty-four hours. This delayed reaction is in itself an evidence of the serious mischief done to the nervous centres. These changes are often sud-

[1] Read before the Practitioners' Society of New York, April 7, 1899.

den and correspondingly dangerous. Although more frequently seen with chloroform, they occur often enough with the safer anæsthetic, ether, to place us on our guard. In this connection the interesting experiments of Thomson and Kemp on the influence of prolonged etherization on the circulation of the kidney in ultimately arresting the renal secretion are not without their practical lesson. It is often a question also how much the forced method of administering ether, and the necessarily resisting struggles of the patient, may have to do with inviting contributive shock, as compared with the more prudent way of coaxing the patient to take the anæsthetic quietly and thus better save his energies for his coming ordeal.

It is not inconsistent with carefulness that we should do our work more quickly. We should shorten not only the period of anæsthesia, but that of the operation itself. To do whatever is absolutely necessary, and do that as quickly as possible, is the primary consideration. Of two methods of procedure, the one that takes the shortest time should always be preferred. Oftentimes a very few moments will settle the issue one way or another. It is the proper elimination of these apparently trivial points in great operations which should be more seriously considered if we would take the fullest advantage of our present high opportunities. In a grave and prolonged operation it is much safer to divide the work into two periods if possible, rather than strain a point to finish it in one. On the contrary, there should be no encouragement for those surgeons who for mere convenience' sake do three or four different operations on the same patient at one sitting.

The prevention of a great deal of unnecessary shock is often possible by a proper appreciation of the peculiar and ofttimes alarmingly responsive sensitiveness of certain regions of the body. This condition is not only manifested in such particular instances by the amount of ether or chloroform required for profound anæsthesia, but is also evidenced when the particular tissues concerned are severed, torn, or crushed. The cutting of large nerves during an amputation is attended with lowering of the force of the pulse-beat and with depression in animal temperature. Erichsen alludes to the same sinking of the pulse during section of the spermatic cord in castration. Pirogoff, before the days of anæsthesia, saw two men die on the operating-table from shock the instant the thigh bone was sawed through for amputation. It has also been frequently noticed that operations upon the perineal and anal regions are liable to produce shock out of all proportions to the magnitude of the wound. The reasons for this apparent susceptibility are the violent stimulation of sensory peripheral nerves supplying the parts involved in the operation or injury, and their direct connection with the lumbar enlargement of the spinal cord. A similar explanation applies to all other hypersensitive parts of the body. The involvement of the trigeminus nerve in the operation of extirpation of the upper jaw is attended by very severe shock, and not infrequently the rasping of the deeper parts of the resulting excavation and the consequent laceration of the numerous nerve filaments in overzealous and protracted efforts to remove all suspicion of malignant disease, very often settles the question whether or not the patient will ever react. "It is recognized," says Cheever, "that long-continued and large dissections on the front and sides of the neck are especially fatal." In the prolonged exposure and rough handling of the abdominal viscera, and in the brain jar of many of the cranial operations, we have many well-recognized and frequent causes for an unnecessarily increased mortality. In connection with the latter operative procedures it is quite remarkable to notice the different rate of mortality between the earlier and the later cases, which has been largely due to the replacement of chisels and hammers by electric saws and necessarily quicker sections.

If so much can be said in a general way in favor of more time-saving during the operation when varied conditions are usually forced, and when once commenced the work must go to the finish, what can be said in excuse for the deliberate, tedious, and oftentimes fussy dressings that must be completed whether or no before the patient is warmly tucked in his bed? What has been said concerning care, safety, and speed in operation applies with still more force to this first dressing. Very often the matter of sewing up a large wound to escape union by second intention directly invites death by first intention. In regard to asepsis, there is no reason why a wound cannot be as quickly and as safely protected with the simplest coverings as with the piles of gauze and yards and yards of bandage which necessitate the rolling, lifting, and twisting of a helplessly exhausted subject at a time when he should have every advantage of quietude, rest, and warmth.

Whatever explanations we may offer as to the real pathology of shock, we must acknowledge from a clinical point of view that, all other things being equal, those patients who are the shortest time on the operating-table have incomparably better chances for recovery than those who are subjected to the present fashionable details of tediously deliberative technique. Quick reaction follows quick operations. The two hold a proper relation to each other for good. On the contrary, the longer the operation the longer is the reaction delayed. How often do we hear that the patient failed to rally after hours of fruitless stimulation! This is very often unavoidable, but sometimes if the surgeon while at work thought more of his patient than of the operation, the results might be very different.

There is another point also which may deserve passing reference in that connection, and that is the influence of certain positions of the patient in inducing or contributing to shock. The semi-recumbent posture in all prolonged operations is always more or less dangerous in this regard. Sims' position and that of Trendelenburg are also open to similar objections. The latter is particularly bad when the patient is obese and the necessarily heavy abdominal contents crowd by force of gravity on a laboring diaphragm. It is unfortunate also that most of the intestinal and bladder operations, which are often necessarily tedious, require for their easier performance this radical reversal of relations of the different vital organs.

The conclusion of the whole matter would seem to be that we are sacrificing precious time to unnecessary detail. What seems to be requisite now is not so much that we shall operate better, but that we shall do our work quicker. If the present perfection of technique can join issue with greater economy of time, the lesson of the hour will be profitably learned. Ordinarily there is no concern for exhaustion from hemorrhage, as the greatest care is always taken to seize the vessels the instant they are severed, but with nerve injury the effect is not so immediate generally as to force it upon the attention of the operator. The sentinel of pain is asleep, and vital energy retreats unchallenged in the very face of the enemy. If the nerve taps could be counted as easily as the blood jets, we would be correspondingly careful to guard against proportionately damaging results.

The direful effects of prolonged operations are often manifest not only in the appalling suddenness of overwhelming collapse, but in the proportionate length of time that proper reaction is delayed. These are the special dangers against which we must be constantly on our guard. There is apparently no warning of disaster. It is the explosion and ruin all in

one. It is seemingly inexplicable and therefore unexpected. If they do not die outright, these patients seldom rally beyond a certain point. We keep them alive for a few hours, and impliedly regret that the patient should have missed what might have been under other circumstances a splendid chance of ultimate recovery.

8 East 66th Street.

## HÆMOSTASIS IN INTRAPELVIC SURGERY.[1]

By A. C. HEFFENGER, M.D.,

United States Navy,

Member of the State Board of Medical Examiners of New Hampshire, of the New Hampshire Medical Society, the New Hampshire Surgical Club, the Strafford District Medical Society, etc.

In discussing the subject under consideration I shall not detail the views or experiences of other surgeons, but rather base my remarks upon individual observations in fifty-four of my own cases, and speak in such a plain, practical way that every one within my hearing may so clearly understand the technique, which is, of course, by the abdominal route, as to be able rapidly and skilfully to carry out the various steps either as operator or assistant.

As the title of the paper may seem somewhat ambiguous, it may be well to state that by hæmostasis in intrapelvic surgery is meant the control of operative hemorrhage between the pelvic peritoneum above, and the mucous surfaces of the bladder, vagina, and rectum below. Practically four arteries supply blood to this region, viz., the two ovarian and two uterine; and one or all of these may be divided in intrapelvic operations. The vaginal, the superior vesical, and the superior hemorrhoidal arteries are also liable to injury when pelvic tumors or growths invade the vault of the vagina, or upper segments of the bladder or rectum, so that familiarity with their course and distribution is demanded.

All the pelvic arteries anastomose freely with both those on the same side and their fellows of the opposite side, so that, when divided, hemorrhage does not cease, except in very small branches, unless both ends are controlled. Pozzi has stated that he saw an American surgeon do a hysterectomy without using hæmostat or ligature, as the rapid contraction of the divided arteries practically controlled hemorrhage till the operation was completed, when it is presumed the ligatures were applied. This statement passes my comprehension, yet coming from such authority it must be true. Of course all vessels may be simply clamped during the steps of a hysterectomy, and ligatures applied after the uterus is removed, and I have found it advantageous in some cases to pursue this course. It may be stated, however, without fear of contradiction, that absolute control of hemorrhage is the keynote to successful intrapelvic surgery, and can be obtained only by the skilful and thorough use of the means, which may be summarized as follows, viz.: hæmostatic and traction forceps or clamps of various forms and sizes, ligatures of different materials and various modes of application, suturing, digital and sponge compression, gauze packing, hot water, hydrogen dioxide, and the actual cautery.

Hæmostats of four sizes, the clamp portion ranging from one to two inches in length and being both straight and curved, meet all requirements for clamping, while three sizes of tumor traction forceps, that is, large, intermediate, and small, are all that are needed in that line.

Ligature and suture material should be confined to catgut, tendon, and silk, and of the three catgut meets the greatest number of requirements. Silk, of course, is the strongest, can be made absolutely sterile, and rarely slips from position; but its fatal objection is that it remains as a foreign body in the tissues, and is liable sooner or later to cause repellant suppuration. Some of the worst pelvic abscesses it has ever been my fortune to see have resulted after many months of apparently perfect convalescence, from some wandering microbe building his nest in the strands of an encysted silk ligature.

There can be no question that the buried ligature or suture should be absorbable, or capable of disappearing by organization as soon as its work is done, for only in this way can subsequent suppuration be surely avoided. Both catgut and tendon will meet these requirements, but the difficulty with the first is to get it sterile, and with the latter to get it of fine sizes, yet of sufficient length and evenness. Personally I prefer catgut, and when sterilized by both formalin and heat no bacterial cultures have been obtained from it. The formalin should be carefully washed out; otherwise the gut is rendered too hard and resistant. No suture or ligature should remain in the tissues unorganized after fifteen days. Small sizes should completely disappear by the seventh day, and large sizes from the twelfth to the fifteenth day. For the last five years I have used catgut with a free hand in intrapelvic work, two or three yards of it in some instances, and only in two cases has suppuration resulted. The catgut used in these two cases was sterilized by a New York manufacturer of much repute, and investigation elicited the fact that a new sterilizer failed to yield the necessary 250° F. of temperature for sixty minutes among the tubes at the bottom, and a number of septic cases resulted from the use of this material in New York and Boston as well as in Portsmouth. In justice to the manufacturer, however, I must state that in no other instance have I had occasion to find fault with his suture material, and am using it now with perfect confidence.

Ligatures when applied to the divided end of an artery should be placed well beyond the controlling hæmostat, two turns being taken in the first part of the tie, and firmly set up, the knot being finally secured by a single turn. If the artery is small, the ends may be cut short at once, but if it is large, it is best to secure the free ends of the ligature with a small hæmostat, which is thrown to one side till the final steps of the operation, when, if all seems secure, the ends are cut short.

In tying an artery in its continuity, a ligature passer is needed, and I know of none better for this purpose than the Cleveland needle. The Germans have for some years used the Thiersch spindle, and many of our own surgeons use various carriers, modifications of the old aneurism needle, but none of these instruments can compare in all-round utility to the carrier designed by Dr. Cleveland, of New York, and generally known as the Cleveland needle. Whether it be for single or multiple and continuous mass ligatures this needle has proven more satisfactory in my hands than any other carrier.

When a large number of small vessels are bleeding, or when a vessel is bleeding in a mass of tissue and is not easily caught by a hæmostat, snaking or pursing the tissues together by in-and-out suturing and tying is the most effective method of completely and securely arresting hemorrhage. For this purpose I use the Martin needle, as it has a large eye for taking catgut, and a quick curve for going in and out of tissues. The Kelly needle is also very efficient when the very smallest sizes of catgut are used, but its small eye necessitates a silk carrier when medium or large sized ligatures are used. Small hemorrhage from surfaces

[1] Read before the New Hampshire Surgical Club and New Hampshire Medical Society.

which are ultimately to be sutured may be temporarily controlled by hæmostats, and finally arrested by the judicious placing of approximating sutures.

Digital compression may become a necessity during the course of an operation from the breaking or dropping of hæmostats, or an insufficiency in their number, but should be avoided if possible, as all handling of tissues causes additional risk of infection. Sponge compression and gauze packing are exceedingly useful in arresting capillary oozing, especially when of large extent. Hot water at a temperature of from 110° to 120° F. is also very efficient in this kind of hemorrhage, and may be either poured on the bleeding surface or applied with a gauze sponge. Hydrogen dioxide will likewise be found useful on small areas, and should be applied pure on a small pledget of gauze.

When tissues are divided rapidly between hæmostats, and it is not deemed wise to stop for ligaturing, traction, either direct or by twisting and pulling the tumorous mass to be removed, with strong traction forceps, controls to a more or less degree the flow of blood till plenty of room is obtained to apply ligatures securely. Finally it may be necessary to arrest hemorrhage from small vessels when the tissues are friable and septic, and in this case the actual cautery is to be preferred.

**Securing the Ovarian Arteries.**—In order properly to secure the ovarian arteries, it is necessary to have an accurate knowledge of their anatomy. These arteries arise on the left side from the renal artery and on the right from the front of the aorta. They descend with the ureters to the brim of the pelvis, and enter the pelvis through the suspensory ligament of the ovary. On reaching the ovary a branch is given off which passes upward to the Fallopian tube, and follows its under surface to the uterus. The main artery sends branches to the ovary, and then runs directly inward to the side of the uterus just below the round ligament, where it sends a branch to connect with the tubal branch, gives off the artery to the round ligament, and finally anastomoses with the terminal branches of the uterine artery.

Now upon examining the structure of the broad ligament immediately below the infundibulo-pelvic ligament, a clear or non-vascular space will be found, and if a ligature carrier is passed through this space, and a ligature pulled through and properly tied over the upper margin of the suspensory ligament, the ovarian circulation of that side will be completely arrested. If the tube and ovary of that side are to be removed, two additional ligatures are, as a rule, all that are required. One is passed around the tube close to the uterus, and the tube freed on the outer side of the ligature; and a second ligature is applied where the anastomosis of the ovarian with the uterine artery takes place; and then the tube and ovary may be freely cut away. Any slight bleeding which may come from the cut margins of the broad ligament is quickly arrested by inverting the edges of the anterior and posterior layers of peritoneum and overwhipping the line with fine catgut.

In large tumors of any kind of the uterus, ovaries, tubes, or ligaments, enlarged veins, often great sinuses, are more or less freely encountered, and it is highly important that they should be securely controlled with as little loss of blood as possible. When very large they should be double-ligatured and divided individually, but when of moderate size and close together they may be double-ligatured in small groups and divided as encountered.

In distinctly pediculated tumors, when the pedicle is flat and thin, and the vessels are plainly visible, the pedicle may be secured by a continuous double in-and-out mass ligature, or the vessels secured by interrupted ligatures, or finally the pedicle may be double-clamped and cut between the clamps, the ends of the vessels being tied individually, and the peritoneal margins inverted and overwhipped with catgut.

**Securing the Uterine Arteries.**—The uterine arteries are much more difficult to secure than the ovarian, and no one should attempt to tie them without an intimate knowledge of their course and relation. they arise from the anterior trunk of the internal iliac artery, and run inward to the side of the neck of Te uterus, reaching that organ from a half to three-quarters of an inch above the vaginal attachment. These arteries are greatly convoluted and lie loosely in the cellular tissue in the lower folds of the broad ligament, so that they may be lifted and pulled well out of the way of other structures where ligatures are applied. They are accompanied by two or more large veins, and the ureters will be found passing immediately beneath them, though one of the veins often lies below the ureter. After reaching the uterus they run up its side to the cornua, where they anastomose with the ovarian arteries. But one important branch is given off during the passage upward, and that is opposite the internal os. These arteries do not lie immediately in contact with the uterus, but are found in the cellular tissue about one-twelfth or one-twenty-fifth of an inch away. These arteries are not tied except in partial or complete hysterectomy, so that their control is part of the technique of uterine extirpation, and must be considered more or less in that connection. A few years ago many operators sought to ligate these arteries as the first step in hysterectomy, but now they are ligated only when reached in the progressive steps of the extirpation. Securing the vessels in hysterectomy for three different conditions will be taken as general illustrations. In the first place let us take a case of simple uterine fibroma, in which the uterus is only moderately enlarged and is freely movable, with no adhesions. Three main ligatures on each side are to be relied upon practically to control the circulation. The left side of the pelvis is first attacked and a ligature applied to the ovarian artery at its point of anastomosis with the uterine, which also includes the uterine end of the Fallopian tube; the tissues on the uterine side are then clamped, and the included area is cut down to the round ligament. Another ligature is then thrown about this ligament and including the tissues just below, the clamp is applied on the uterine side, and the included segment cut well down toward the uterine artery. The two layers of the broad ligament are now separated by blunt dissection, and the uterine artery is sought for with the fingers. It will soon be found strongly pulsating, and can be separated from its veins, lifted free from the side of the uterus, and tied a quarter or three-eighths of an inch in its course up the uterine neck, thus avoiding injury to the ureter. The uterine veins are then double-tied, or tied and clamped.

Now the same course of procedure may be gone through with from above downward on the opposite side, and the uterus dissected free from bladder, vagina, and rectum, or amputated through the neck; or the operation may proceed from left to right, the neck of the uterus being freed and amputated, the organ pulled well to the right to expose the uterine vessels, which with the ovarian are secured in inverse order. After the uterus is removed from the pelvis, all additional bleeding points are at once clamped and tied, and the main arteries are secured by a second ligature. In this operation it is noticed that the tubes and ovaries are left in, and the space between them is covered in by suturing the anterior and posterior layers of peritoneum together, the vagina or amputated cervix, as the case may be, having been first sutured.

The next illustration will be a case of cancer of the

cervix, the disease not extending beyond the adjacent areolar tissue and contiguous parts of the broad ligaments—in other words, a fairly good operative case. Here the uterus with its adnexa and all other pelvic tissue consistent with the integrity of the ureters, bladder, and rectum should be removed. A sweeping extirpation is in order, and the operation is begun by securing the ovarian vessels on the left side by a ligature through the clear space and over the infundibulo-pelvic ligament The clamp is then applied on the ovarian side, and the included region cut through. A second ligature is now thrown around the round ligament including the anastomotic zone, a clamp applied on the uterine side, and the intervening structure divided well to the outer side of the uterus so as to take in the greater part of the broad ligament. The uterine artery is now searched for as in the first operation, and, when found, traced well back to its origin. Great care should be taken to separate it from the ureter. The tissues should be carefully rolled between the fingers, when the artery will be found round and pulsating, and the ureter flat, hard and ribbon-like. The artery is lifted clear and tied on the outer side of the ureter, near its origin from the anterior branch of the internal iliac. The veins are next carefully separated from the ureter, some being found above and some below, and double-ligatured. The peritoneum having been incised across the front and back of the uterus, and the neck peeled out and cut free from the vagina, the same steps may be taken on the right side of the pelvis, or the vessels may be secured and tissues divided inversely as explained in the first operation.

For the third illustration we will take a large myomatous uterus, firmly impacted in the pelvis, with tubes and ovaries beneath the mass, and all special anatomical outlines masked by general visceral adhesions. This is a picture before which even the boldest operator may hesitate as to what is to be attacked first. It has been my rule in these cases to begin on what seems to be the easiest point on the left side of the pelvis. To reach the ovarian vessels, it is necessary to get under the tumorous mass, and that is best done by carefully separating the visceral adhesions, probably binding the sigmoid flexure to the upper surface of the tumor, then with scissors or fingers, according to the density of the adhesions, gradually separating the mass from the rectum and pelvic brim. Ruptured vessels which bleed freely should be clamped and tied, or, if that is impracticable, the bleeding area is included in one or more puckering catgut sutures, as the case may require, and the enucleation continued till the ovarian vessels are reached and secured, and the infundibulo-pelvic ligament is cut. Now by making strong traction to the right the mass may be tilted up, and rapidly shelled out of its cellular bed. The round ligaments are soon found like tense cords, and after they have been double-ligatured and divided, or ligatured and clamped, the tumor can be still farther rotated to the right and the uterine vessels found and secured. The peritoneum is next girdled around the uterus on a level with the round ligaments, and peeled down in front till the bladder is free, and behind till well down on the neck. Freeing the vesical peritoneum permits the bladder to drop down out of the way and carry the ureters with it. The greatest care must be taken in these cases to avoid including the ureters in the uterine ligatures, or otherwise injuring them. The cervix is next amputated from left to right, the tumor pulled farther to the right and rolled out of the pelvis, and the right uterine and ovarian vessels are secured as described in previous operations. All ligatures are now carefully inspected, and the large vessels doubly secured by a second set. Bleeding points are picked up and tied, and general oozing is arrested by the means previously given.

**Secondary Hemorrhage.**—The danger of secondary hemorrhage should always be borne in mind, for it may occur any time within a week or ten days. Kelly enumerates the chief causes of secondary hemorrhage as follows, viz.: (1) defective tying; (2) cutting too close to a ligature; (3) undue traction on a ligature after tying; (4) the shrinkage of the tissues within the grasp of the ligature; (5) an extensive capillary oozing. To these must be added the softening and untying of catgut ligatures, even though well tied, and this is especially apt to happen if the ends are cut too short. So far I have never seen a secondary hemorrhage of sufficient degree to produce general symptoms, so I shall have to give you the train of symptoms as given by that masterful surgeon, Dr. Howard Kelly: (1) Sudden quickening of the pulse and diminution in volume without apparent cause, or even an entire loss of pulse; (2) quickened sighing respiration and the use of the extraordinary muscles of respiration; (3) increasing pallor and a pearly conjunctiva; (4) cold, clammy skin; (5) vertigo; (6) restlessness, throwing the arms and legs from side to side; (7) desire to be raised in bed (orthopnœa); (8) pain in the abdomen often severe; (9) vomiting sometimes. The author, after giving this summary, depicts the fatal history of a case of secondary hemorrhage in such a terribly realistic manner that any operator who reads it will double his vigilance in future to avoid being responsible for such a calamity. In eighteen hundred abdominal sections at Johns Hopkins Hospital, there were only eight post-operative hemorrhages, and one death.

As soon as secondary hemorrhage is evident, the abdominal wound is opened, the bleeding vessels are sought out, clamped, and religatured, blood and blood clots are removed, the abdominal cavity is flushed with hot decinormal salt solution, the wound closed or drained as the case may demand, and a pint of saline solution transfused under each mammary gland. The patient in the mean time has had hypodermics of strychnine and whiskey, and an enema of two ounces of whiskey and six ounces of beef tea is next given, and she is placed in bed with the head lowered and surrounded by hot bottles.

The pulse will be found from 140 to 160, and it will be several days before it falls below 100, though the patient otherwise may be in good condition.

PORTSMOUTH, N. H., March, 1899.

---

## THE EXERCISE TREATMENT IN TABES DORSALIS.[1]

BY ALFRED WIENER, M.D.,

ADJUNCT PROFESSOR OF NERVOUS DISEASES IN THE NEW YORK POLYCLINIC.

A GREAT many highly lauded forms of treatment have been employed in the management of tabes dorsalis. Many have been given up in disgust, others are still used with varying success. Although no specific value can be attached to such measures as balneotherapy, hydro-therapy, electro-therapy, and dietetic treatment, we must nevertheless admit that a beneficial influence is exerted by them upon the general welfare of our patients. Their various nerve functions are strengthened, and their complaints in the way of subjective sensations are decidedly ameliorated. Surgical interference—I refer to the nerve-stretching procedures—so far as I have been able to ascertain, has been abandoned. Motchutkowski's suspension method has had its trial and been found to be positively harmful. Whether the mildly beneficial influence which is ex-

[1] Read before the section on neurology and psychiatry of the New York Academy of Medicine, April 28, 1899.

erted by this treatment depends upon its suggestive effect or not, it should not be employed so long as harmful results have been reported. Another method, which is truly barbarous, that of Bonuzzi and Blondel, in which a forcible stretching and flexing of the body are advised, has been entirely given up. The Hessig corset is of advantage if we wish to make use of a support to correct deformity. That it exerts any continuous stretching effect upon the spinal cord, I am unwilling to believe. So far as antisyphilitic treatment is concerned, I think that most of us have come to the conclusion that a radical improvement in the objective symptoms of tabes is not obtainable.

Those who are familiar with the pathology of this disease do not look for a specific which will cure this local process. Still it should be our endeavor to find the ways and means by which we can at least alleviate the patient's suffering. It is with some satisfaction that the neurologist is at last able to announce the fact that limitations must be placed upon the idea that tabes dorsalis cannot be benefited in any way. Those who will employ the treatment so carefully worked out by Fraenkel, of Heiden, Switzerland, will find the same brilliant results attending their efforts that have followed my own. I refer to the treatment of ataxia by means of compensatory gymnastics. Abroad this is now an established form of treatment, highly recommended by Leyden, Goldscheider, and other prominent neurologists.

Ataxia is surely one of the most prominent symptoms in tabes. When present to any great degree, it is one of the most distressing of the symptoms which these patients suffer from. It continues for years, advancing sometimes very slowly, and at other times making such rapid progress that walking is an utter impossibility. In compensatory gymnastics we have at last found a method of treatment by means of which these patients can be so greatly benefited that they have apparently recovered their normal gait.

For the last seven months, I have busied myself in making a careful trial of this treatment. My results have been so encouraging that I no longer hesitate to report them. I purposely have chosen very severe cases, and those in which there was not the slightest element of a doubt that they were suffering from tabes dorsalis. My own experience is limited to ten cases. Of these, three have been under my observation for almost six months, the rest at varying intervals for four, two, and one month. In order to give you some idea in what condition some of these patients were at the beginning of their treatment, and just what results can be accomplished, I append here the history and results of three of my cases:

Case I.—Referred to me by Dr. B. Sachs. Mr. W. H——, aged forty-three years. The only severe illness this patient can remember having suffered from, is typhoid fever in his early youth. He has always led a more or less sedentary life, and, although freely indulging in alcohol and tobacco, he denies that there has ever been any excessive dissipation. There is absolutely no history of syphilis obtainable. He has always been a sufferer from stomach and bowel disturbances. In December, 1891, the patient was caught in the Sage explosion. The chair upon which he sat was completely demolished, and he was thrown over six feet, sustaining apparently no physical injury, but on the other hand a severe nervous shock. In 1892, he was thrown from a horse at a military review, and struck with the front portion of his body against a fence. He suffered only slight bruises, and was up and about directly afterward. The first symptom of the present complaint was noticed in 1895. The patient was crossing the ocean at that time, and he experienced a distinct numbness and paræsthesia in both upper extremities. It was especially acute in the left hand and forearm, and confined almost exclusively to the ulnar distribution. While on the continent this became more noticeable, and great difficulty was experienced in carrying and handling hand baggage. The patient now became alarmed, and placed himself in charge of a homœopathic physician. No special benefit having been derived after eight months, he ceased all treatment until 1898. At that time new features presented themselves. The paræsthesia and numbness had spread to his lower extremities, and an awkwardness in his gait became very apparent. His upper extremities had also grown considerably worse. In attempting to use the telephone one day, he suddenly became puzzled as to the location of the ear piece, which he was holding in his left hand. In looking for it he discovered that he had placed it over his chest. The patient now consulted Dr. B. Sachs. The examination made at that time proved that this gentleman was suffering from tabes dorsalis, with a very marked ataxia in both upper and lower extremities. The ataxia in the lower extremities while under Dr. Sachs' observation became so marked that the patient was able to walk only very short distances, and then only with the assistance of a cane. With his eyes closed it was absolutely impossible for him to perform a single co-ordinated movement, either when lying down or standing up. Although the left patellar reflex was present at the first examination it soon disappeared. Areas of incomplete anæsthesia were found on the plantar portion of both feet, on th external surface of both thighs, and in the ulnar distribution of both upper extremities, especially on the left side. The location sense was very much disturbed. In addition to these objective symptoms, th patient had a number of other prominent tabetic symptoms, which, however, it will not be necessary to mention here

Case II.—Mr. A. R——, aged forty-two years, married a second time. He had one child by his first wife, with whom he lived twelve years. He is married to his second wife three years, but they have had no children. He denies syphilis or any excessive indulgence in alcohol or tobacco. His family history tells of miscarriages which his first wife suffered from, and a doubtful venereal affection which he had in his early youth. The presence of a syphilitic infection at that time is, therefore, very probable. For the last seven years this patient has experienced slight difficulty in walking, but never to such a degree that it interfered with his occupation as a waiter. At times during these seven years he suffered from attacks of uncontrollable vomiting. These attacks still present themselves. Recently I had occasion personally to observe the patient in such an attack, and convinced myself that it was an ordinary attack of gastric crisis. During the last five years, the patient has suffered only slightly from pain. Three months ago, without any apparent cause whatsoever, he suddenly began to walk very badly. His gait grew worse from day to day, until finally he was compelled to give up his occupation. I saw this patient for the first time eight weeks ago, and he presented the following status: Typical Argyll-Robertson pupils, unequal in size, and the left the larger one of the two; patellar reflex absent on both sides; incontinence of urine; numbness in both feet, with extensive anæsthesias in both lower extremities and the trunk; a very marked and delayed response to the sensation of pain. There is complete impotence. The upper extremities are entirely free from paræsthetic disturbances and ataxia. As regards walking, he was utterly unable to walk alone. He was led into my clinic firmly supported by his wife, and a stout stick held in one hand He was incapable of performing a single co-ordinated movement with his lower extremities. Such an act as arising from a

chair, or standing without support, was a physical impossibility.

Case III.—Mr. A. N——, aged forty-four years, unmarried, insurance broker. He admits having had syphilis fifteen years ago. He denies any overindulgence in alcohol or tobacco. About one year ago, he observed that he was somewhat awkward in descending a stairway. This was especially noticeable in the dark. When he walked any great distances during the day, he also experienced some difficulty. About four months ago, this gentleman underwent an operation for hemorrhoids. He was confined to bed for one week. As soon as he was allowed to get up and around, he found it impossible to walk without the assistance of a cane. He also began to experience some difficulty with his bladder. He could not urinate freely. He complained bitterly of stiffness in both of his lower extremities. Anæsthesia almost complete was found in the right foot, leg, and thigh. The sensation of pain was very much delayed. In his left lower extremity the same condition was present, but not to so marked a degree. In addition to his tabetic symptoms, this gentleman has lately begun to present symptoms which point toward the development of a paralytic dementia.

With the exception of the ataxia, I have purposely refrained from going into any details regarding the various symptoms present in these patients. They do not concern us in this paper.

Each patient was carefully taken in hand by myself, and treatment thoroughly persevered in and carried out under my guidance. Contrary to the Fraenkel method, I made use of no complicated apparatus. Nothing was employed which could not be found in any physician's office, or could not be easily obtained or constructed by the patient himself. It was found advisable, in all my severe cases, to teach these patients to perform their various exercises while lying flat upon the back; at first with their eyes open and then with their eyes shut. I will not attempt to enumerate all the different movements which I taught them. Each case will suggest to the experienced physician different movements. You will soon learn to know that exercises which you may have employed in the beginning in one case will not at all answer the purpose in the second. As soon as one finds that the patient is becoming more and more adept in performing his exercises while lying down, then the second stage of the treatment is begun. The patient now sits upon a chair and learns to perform the various exercises assigned to him. When these are well performed, the third stage of the treatment is entered upon. The patient now learns to stand and walk. At the same time he begins to perform difficult and complicated movements. My methods of procedure in private cases is as follows: First of all, I treat all severe cases in bed, and strengthen both mind and body through hydrotherapeutic procedures, diet, and general tonic treatment. I make it a practice to elucidate and explain all the details of the treatment to these patients. What advantage this psychical effect has, is shown by the more rapid advance made by the intelligent ones than the ignorant. This is clearly shown in Case III. In this individual I have suspected a beginning mental disturbance. There has been very little improvement in his condition of late. As soon as I feel that my patient is strong enough I begin with the gymnastic treatment above mentioned. It is advisable at times to change the exercises, or use some other method of procedure in performing them, so as not to allow the treatment to become monotonous. I constantly call the patient's attention to his improvement, demonstrating to him that what at first was difficult to perform at last becomes an easy matter. I do not under any circumstances let these patients perform their exercises entirely alone. They should be under the control of a competent observer who will correct all errors at once, and insist upon precision in all movements. I personally feel that the physician should be the observer and teacher. You will find that considerable judgment and tact are necessary in order to devise the various exercises. If you intrust this to a nurse or incompetent person, he is apt to go at it in too schematic a way. The more you ask of such a treatment the more difficult the technique becomes. Therefore, only one who thoroughly understands the functions and workings of the various muscle groups is capable of conscientiously conducting it.

All my patients have shown the most encouraging results, and especially in the three cases here reported. In Case I., after six months' treatment the patient walks with the greatest ease and any reasonable distance that one might expect of him. He walks over obstructions placed in his way, without stumbling, and walks up and down stairs without assistance. He can walk backward, one foot behind the other, with only the slightest awkwardness. He can stand on one foot and perform various exercises with the other with the greatest ease. There is still some room for improvement; but when one considers what this patient was capable of accomplishing in the beginning, and what he is doing now, I think that we must admit that the result is excellent. In Case II., after two months' treatment the patient comes to my clinic alone. He uses a cane, but can walk without it. He can arise from his chair without aid. He can walk one foot in front of the other, along a straight line, and the same backward, and appears only slightly awkward. He can stand on one foot. This patient is rapidly improving, and I am confident that within two months more he will almost have regained his normal gait.

In Case III., after three months' treatment the patient walks without a cane. He can perform all his various exercises perfectly when lying down, and is rapidly losing his ataxia and awkwardness when walking about. With this patient I am beginning to experience some difficulty in the training, on account of his failing mental condition.

Before drawing any practical conclusions, it would not be unwise to offer you some explanation for the scientific basis of the treatment. Once for all let it be understood that it is not a form of gymnastic exercises indulged in to strengthen muscles. We all know that in a pure case of tabes dorsalis there is absolutely no paralysis, no atrophy, and nothing in fact to suggest that the muscles are primarily at fault. It is a systematic exercise practised for the purpose of helping these patients to learn to co-ordinate properly, to lose their uncertainty, and again gain confidence in themselves.

The explanation which I offer here is the one accepted now by Fraenkel himself, and was first proposed at the congress held at Moscow in August, 1897. In order fully to understand this explanation, let us review for a moment the two theories which exist in reference to ataxia. The one known as the Charcot-Erb theory recognizes a centrifugal co-ordination system of fibres in the spinal cord, and establishes the hypothesis that spinal ataxia is due to a primary lesion of these fibres. The other, known as the Leyden-Goldscheider or sensory ataxia theory, establishes as the main principle that the co-ordination of movements in the healthy state depends directly upon the integrity of our sensory sphere. Leyden and Goldscheider, in their treatise entitled, "Ueber die Erkrankungen des Rückenmarks und der Medulla oblongata," have explained in detail this theory. It is well worth our while to review their explanation, in order to understand clearly the application of this theory to the exercise treatment. The authors claim that co-ordi-

nation is effected in two different ways. First, the simple synergic movement, viz., for the performance of a simple movement several muscles work together: or several antagonistic muscles may be thrown into action in order to produce a slight restraint, and thus a more harmonious action; or a number of other muscles help along, by means of their own individual action, to carry out or accomplish the movement of a single muscle. These simple synergic movements are undoubtedly localized in the spinal cord. Entirely different is the second form, viz., the complicated or chosen co-ordinated actions. The individual muscles and the synergic acting muscles functionate in such a manner as to produce some intended movement. Of course, this can be accomplished only with the help of a complicated cerebral process. First, there must occur the idea of a movement; secondly, the impulse of the will, and finally, a motor expression which results in a muscle contraction.

There is no doubt that sensation plays a very important rôle in all complicated movements. Still the same can be accomplished almost as well with the help of our perceptive sensory faculties, when necessary. Take, for instance, the individual suffering from anæsthesia in hysteria, or in fact anæsthesia from other causes; surely they are not all ataxic. Histological and pathological researches have established the fact that when the nerve fibres or cells in the central nervous system are once destroyed, they are never again regenerated. In tabes dorsalis the sensory tracts in the spinal cord are destroyed; nevertheless tabetic patients learn by a systematic education in compensatory gymnastics again to control their various movements. The only explanation that can be offered for this fact is that these patients are compelled to call upon other perceptive faculties to supplant this lost sensory conduction. It is evident, therefore, from the above, that the good effect of the exercise treatment of tabes can be explained only on the theory of the sensory origin of ataxia. If we do not assume this theory, it would be impossible to account for the remarkable improvement in the gait of these patients. As we cannot suppose that there has been any regeneration of nerve fibres, the Charcot-Erb theory is not applicable. If this explanation is acceptable, we have at last found a treatment based not upon empirical methods, but upon carefully ascertained scientific facts.

Much more might be said in reference to this form of therapeutics; but I feel that I have sufficiently called your attention to a form of treatment that is absolutely beneficial in the ataxia of tabes dorsalis. In conclusion let me say that I hope you will give this method a fair trial. If you do this I am confident that you will be just as much encouraged and satisfied with your results as I have been.

## HYDROPHOBIA A DISEASE EASILY CURED.

By BEVERLEY OLIVER KINNEAR, M.D.

NEW YORK.

The subject of hydrophobia has attracted much attention from the medical fraternity, especially during the last nineteen years. It may be fairly divided into three heads: (1) Is it a disease at all? (2) Is it a nervous disease? (3) Is it a disease due to an absorbed poison?

It appears to the writer that these three queries cover the present ground of discussion of this malady. The first question may be answered in several ways. Do those who take this stand infer that there is no poison generated in the mouth of the so-called mad animal, to be absorbed by the person bitten? Or do they infer that no such set of symptoms as compose an attack of the disease can be induced by the bite of an animal lacerating terminal nerves, causing an irregular cicatrix and thereby generating central nerve-cell irritation, and responsive muscular and sensation disturbance? Or do they mean that fright alone will excite all the well-recognized symptoms of an attack? Or finally, do they suggest that the statements of a host of honest and intelligent observers count for naught against their opinion, simply because they themselves have never seen a case of the disorder? It would appear unnecessary to enter into a discussion of this query more profoundly until these questions are answered.

Is it a nervous disease? Let us glance at the symptoms of a typical case as presented in the "Twentieth Century Practice of Medicine," in an article upon this disorder. First stage: "Loss of appetite and headache; agitated, depressed, gloomy; ill-tempered, apprehensive, irritable; sleepless, restless, with bad dreams; speaks quickly, with sharp articulation; aversion to fluids and often cannot take solid food; and itching and pain at seat of bite."

Second stage: "Breathing sighing and labored; muscles connected with medulla become affected, inducing spasmodic contraction of larynx and pharynx; hyperæsthesia of sight, feeling, touch, hearing, smelling may all occur, sensation of suffocation causes patient great anxiety; violent homicidal attacks come on, for which the patient expresses regret during quiet intervals; snaps with jaws, both tonic and clonic spasms; aerophobia, and sometimes delirium. The conjunctivæ are injected, pupils dilated, retina hypersensitive to light; pulse full, moderately strong and accelerated—weaker after paroxysms; skin moist and perspiring, and the respiration, during the paroxysms, gasping and irregular. There is also decided thirst."

Final stage: "Death may be preceded by general paralysis; it may take place from convulsive paroxysms and asphyxia, or from coma. The disease may be confounded with hysteria, tetanus, epilepsy, delirium tremens, acute mania, and uræmia."

The testimony of symptoms in all these stages denotes nervous disease predominantly; while the injected conjunctivæ, the full strong pulse, the delirium and maniacal tendency, the hypersensitive retina, and death by coma or convulsions all signify to the writer a condition of hyperæmia of the brain and central nervous system.

During the past eighteen years I have speedily subdued delirium tremens, acute mania, and uræmia temporarily, by contracting the arterioles in the spinal cord and brain and making the general circulation active. Many cases of hysteria can be rapidly cured by expanding the general circulation, thus inducing good nutrition of the body, and at the same time withdrawing the excess of blood from overstimulated nerve centres. Five of these diseases are understood to be nervous, and only one of them—delirium tremens—is due to a poison absorbed. The uræmia of Bright's disease, with the resulting coma, is considered due to a poison acting upon the brain, but Bright's disease does not come under the head of nervous diseases.

According to this evidence, then, hydrophobia may be due either to a poison absorbed, or it may be caused by constant direct irritation carried from the seat of the bite to the central nervous system, giving rise to hyperæmia of nerve centres, and thus an increased function or abnormal action upon their part, inducing thereby all the symptoms of hydrophobia. The fact that there are, in many reported cases and among the early symptoms, itching, pain, and heat at the seat of the bite, would tend to confirm the hypothesis that from the time of the bite by the dog there had been more or less constant direct irritation carried to the central nervous system. But the apparent truth which

is brought out by the foregoing, to my own mind, is, that in all nervous forms of disease the main factor inducing the symptoms is active hyperæmia within, and therefore excessive function of, central nerve cells.

Does the pathology of hydrophobia bear out the above conclusion? The post-mortem examination in man shows general congestion in nerve centres and softening around the spinal cord. Ross, of Manchester, says that tetanus and rabies are alike, the lesions in the former being spinal, in the latter cerebral; and that the nerves leading from the congested centres are congested and enlarged.

Keirle ("Twentieth Century Practice," vol. xv.) says that the lymph glands are always enlarged in rabies. The under surface of the medulla is very vascular, the gray matter of the cord is hyperæmic, the larynx is red, the spleen is dark-red, the liver is congested.

There is practically an immense amount of evidence proving hyperæmia of the nerve centres in hydrophobia.

There is also hyperæmia of mucous membranes and of many organs and glands, which last I have been for many years of the opinion may be due to excitement or hyperfunction of the vaso-dilator nerve centres, and that when conditions of hyperæmia or inflammations are shown by post-mortem demonstration to have existed during life, it is a proof that vaso-dilator nerve centres distributed to the part affected are hyperæmic, and therefore abnormally active. If this is so, then the hyperæmia of glands, of organs, and of mucous membranes noted in cases of hydrophobia would be simply another proof that the cause of the attack was central nerve-centre excitement, or active congestion in the centres.

It appears that the conclusions we may now draw are as follows: (1) The majority of the symptoms denote central nerve-cell excitement. (2) Others testify to the writer, after many years of treatment of nervous diseases and conditions, that there is hyperæmia of the brain and cerebral nerve centres. (3) Treatment which will withdraw excess of blood from nerve centres and at the same time make an active systemic circulation will subdue and cure nervous diseases, whether caused by poison absorbed, by terminal-nerve irritation, by worry, pain, or overexertion, mental or bodily. (4) Pathological conditions evidence hyperæmia of the brain and cerebral nerve centres, as well as hyperæmia of organs and tissues, which may be due to the same central nerve excitement.

If these four propositions be true, the next query which arises is, What is the best treatment, the most rapid and efficient to withdraw the excess of blood in active circulation from the congested brain and nerve centres, and which will at the same time so act as to expel from the body the poison of the disease, if the disease is due to a poison? If it is not due to a poison, how can we most speedily withdraw the excess of blood from the nerve centres and brain, without injury to the patient? Is it best to inject the hydrophobia virus which has presumably caused the disease, and thus secure a hoped-for immunity to the poison already absorbed; or will it be better to excite active secretion from some great emunctory organ, in order to expel the poison if there is one or to attract so much blood to the secreting surface that any excess of blood must perforce be withdrawn from the congested brain and nerve centres—even if no poison exists—and their undue excitement be subdued, the symptoms banished, and a cure effected? There appears to me to be no "halting between two opinions here." It will be far better to expel the poison and withdraw the excess of blood from the congested cerebral area, than to attempt to immunize the party bitten by the further absorption of the same poison which induces the disease. But has such a method ever been used successfully to cure hydrophobia? It most certainly has, and in a large number of cases.

It is hoped that by what has been set forth, and by what is to come, the attention of the profession may be drawn to that which seems to the writer a much more simple, physiological, effective, and less dangerous method of treating and curing this much-dreaded disease, or set of symptoms—whichever one may be pleased to call it—than Pasteur placed before the profession and the public. There is no doubt that a large body of the medical fraternity consider Pasteur's treatment a cause of hydrophobia, instead of a cure; and that it is a danger to be guarded against rather than a cure to be relied upon.

Let us glance at the opinions of some eminent observers. Professor Peter, the greatest clinician France has produced in this century, a man described as the Sir William Gull of Paris—the able editor of *The Medical Journal*—writes: "M. Pasteur does not cure hydrophobia, he gives it." Another physician, Dr. Edward Berdoe, M.R.C.S., says: "So far as any good effects having resulted from the treatment, we know that it has undoubtedly led to the increase of hystero-epilepsy, a disease singularly like hydrophobia." Dr. T. M. Dolan, F.D.C.S., of Halifax, the erudite and independent editor of *The Provincial Medical Journal*, in his book, "Pasteur and Rabies," says: "Not only does M. Pasteur not protect from disease, but he has added a new terror to it by the introduction of paralytic rabies." Dr. Charles Bell Taylor, F.R.C.S., writes: "I regard the so-called wonderful discovery as the most extraordinary delusion which has afflicted men of science for centuries." Professor von Frisch, of Vienna, makes the despairing admission: "The great hopes which the medical world has placed on Pasteur's discovery have not been realized."

"That the Pasteur system is unreliable is evident by the fact that more than three hundred and thirteen persons have died either under the treatment or in spite of it, and as it involves the infliction of infernal barbarities and torture, the sooner the public is made aware that a superior and more humane remedy for hydrophobia has been discovered, the better" (*Herald of the Golden Age*).

Dr. Charles W. Dulles, of Philadelphia, when appointed by the Pennsylvania Medical Society to investigate hydrophobia, stated as his opinion that a large number of deaths from that malady were directly due to inoculation with the virus of what ought to be called "Pasteur's disease."

The following well-authenticated case of Ethel Wilkins, which appeared in the London *Globe*, November 12, 1895, tends to confirm the foregoing judgment: "In October, 1895, the child of the gardener on the Twickenham Park estate (age three years) was bitten on the face by a small fox terrier. The dog was immediately destroyed. There was no evidence that the dog was mad. The child was taken to a physician (Dr. Murphy) to have the wound dressed. At his earnest persuasion the anxious mother (being told that she would have the child's death on her conscience if she refused) allowed the child to be taken to the Pasteur Hospital and put under the regular treatment—inoculation with rabic virus twice daily for the first three days, and then once daily for twenty-one days. On the day she was discharged as cured (though there was no evidence that anything had been the matter with her) feverishness and other symptoms appeared. On November 9th, she was taken back to the Institute, and the doctors then pronounced the case to be hydrophobia and hopeless. She was, however, inoculated twelve times that day—six times on each side. In forty-eight hours this child, three years old, received twenty-four inoculations. The 10th of November, a witness reports

seeing her strapped down on her bed; her hands (which had been left free) had torn her face in her agony."

Added to the foregoing opinions and statements, I have in my own possession a carefully arranged list of three hundred and ninety-four cases treated for hydrophobia by the Pasteur method, from August, 1885, to July, 1898, all of which were fatal. Some were bitten by wolves, some by cats, and the vast majority by supposedly mad dogs. This "quadruple hecatomb," as it is called, is reprinted from a supplement to *The Zoöphilist*, June, 1898. It appears to be undoubtedly correct, as the journals from which the cases were taken are all given, with the dates of their issue. Pasteur's treatment then, according to these representations, has not only not lessened but increased the number of cases of hydrophobia; it has also introduced a new and terrible form of the disorder—paralytic rabies. Further, it is essentially set forth as a preventive treatment only, but of little or no service after the attack has begun or well-developed symptoms have appeared; whereas, the treatment about to be placed before you is simple, is not injurious, may be used preventively, "and will cure if administered not later than the second day of its development, and frequently do so even if not given until the third day." This quotation is taken from some remarks by Dr. Montague R. Leverson, of Fort Hamilton, Brooklyn.

The treatment which I advocate is known as that of the "Buisson" bath. Dr. Buisson (doctor of medicine of the Paris faculty) was called in to a woman suffering from hydrophobia, just one hour before her death. She wished to be bled, and after the operation he wiped his hands on a handkerchief saturated with her saliva. He immediately noticed a small wound upon the first finger of his left hand, and thoroughly cauterized it upon arriving at his office. But on the seventh day pain developed in the wound and rapidly spread up the forearm, following the course of the radial nerve. As the disease progressed, the pain became intolerable; his eyes were extremely irritable, with dimness of vision; his hair seemed to stand erect; a current of fresh air prolonged the paroxysms, there were constant nausea and tightening of the throat, with excessive salivation and incessant expectoration; he had a horror of water, and a constant longing to run and bite. He continues: "For some time past I had been persuaded that a vapor bath was able to prevent, but not to cure, hydrophobia. My thought being occupied solely with death, I sought that which was the most prompt and least painful.

"Being the proprietor of a bath establishment, I resolved to die in a vapor bath (commonly called Russian). I took a Réaumur thermometer in my hands, fearing that the heat I desired might be refused me . . . and at 42° R. (127° F.) I was cured. I confess that at first I refused to believe in a cure which partook of the nature of a miracle. After the bath, I dined and drank with ease, and went to bed and slept well. From that day to this I have felt no sort of pain or uneasiness." The report of his case was given to the French minister of public instruction. Thus this great discovery was simply blundered upon like many another one. "Subsequently over eighty people bitten by rabid dogs underwent his process, and not one died. The theory is simply that sweating (increased by hot drink) opens all the pores of the skin, and all poisonous matter in the blood or in surface wounds is forced out through the pores."

This statement is true, and poisons are eliminated by the sweating process, but there is a deeper truth involved by great activity of all the sweat glands and that is that no gland can secrete excessively, unless a much larger quantity of blood than in normal conditions is passing through it, since all glands, organs, and tissues receive their nutrition from and deposit their refuse into the blood; in the former instance from the arteries, in the latter into the veins. Therefore, when there is an active sweating process carried on by the whole skin, there is an enormous and abnormal amount of blood drawn into these glands; consequently there must be a lesser amount than normal in other portions of the body. Thus, if there is an excess of blood in active circulation in the lungs, in the bronchi, in the pleura, the process of sweating will go a long way toward their relief, and the reason is very clear; because the sweat glands in order to sweat profusely require such a large amount of blood that the excess of blood in the inflamed or congested area is withdrawn, the local congestion relieved, and the patient becomes convalescent.

Now as I have endeavored to show in the early part of this paper that in hydrophobia there is within the brain, the medulla, and the nerve centres an excess of blood in active circulation, giving rise to the attack and the symptoms of the disease—so, when the Buisson bath is used and profound sweating results, not only is the poison, if there is one, eliminated, but also the excess of blood demonstrated to be in the central nervous system by the evidence of symptoms, and also pathological testimony, is speedily withdrawn from the congested cerebrum and centres, and as a result the symptoms are subdued and the patient recovers.

Thus this treatment not only can expel poison, but it also demonstrates a true physiological process, by which the excess of blood may be withdrawn from the abnormally functioning nerve centres. It is simply a beautiful instance of revulsion of blood from the brain and central nervous system to the skin, in the first giving rise to all the horrible symptoms of a greatly feared disease, and in the second this same excess of blood acting as a beneficent and life-restoring vitalizer. It is the difference between a fire in the right place and a fire in the wrong place.

Buisson says: "Vaccinate an infant and give it a vapor bath directly afterward, the vaccine does not take."

This treatment expels any poison, and at the same time overcomes the dangerous conditions induced by the poison, or by reflex irritation from the location of the bite. Suppose there is no poison but only reflex irritation from the seat of injury—then at the seat of injury there must be some local congestion, which for a long time may not become apparent; when it does the symptoms of hydrophobia show themselves. The sweating, being profuse, in this case would not only relieve the congestion of the nerve centres, but also relieve that existing in and about the original wound; thus not only the attack would cease, but would not again recur. My personal opinion is that in some cases there is a poison absorbed, but that in others, especially in cases of severe laceration, the resulting attack may be in the main due to reflex action from the irregular and congested cicatrix, the central nerve congestion being also partially due to the fears of the patient; while the animal which has bitten the sufferer may not have been rabid at all.

But, whichever may be the truth, the Buisson system answers positively all the indications for a radical cure of the disease, while that of M. Pasteur does not; and statistics show that whereas Pasteur refused to receive patients when hydrophobia symptoms had begun, the Buisson treatment cures hydrophobia when fully developed. A notable case is that of Pauline Kiehl, at Paris. She was bitten, with two other persons, by a rabid dog. The others died of hydrophobia. Pauline was taken to Pasteur, who refused to inoculate her on the ground that the hydrophobia had gone past hope. She was taken to the baths in Paris, Faubourg St.

Honoré, where Dr. Leon Petit subjected her to the Buisson treatment, and she recovered. Both as a preventive and cure it is now well known in England, where, according to *The Herald of the Golden Age*, it can be administered at thirty-three different institutions under the superintendence of qualified medical men. It can also be procured at every hydrotherapeutic establishment in the United Kingdom and at over seventy places in India. The governor-general of India has accepted it for all hospitals and dispensaries under government control, and in consequence thirty baths have been sent there from London. Likewise in America it has been tried with pronounced success, as the following cases indicate; and in no instance, as far as the writer knows, has it met with failure.

Rev. James A. Curran closes an account of a desperate case of hydrophobia under his care cured by a vapor bath, and says: "The sufferer has been in convulsions two days—accompanying these convulsions are evident signs of hydrophobia—is apparently at the point of death." (The Buisson treatment was tried with perfect success.) "His cure," he continues, "was remarkable as it was sudden—and he has continued well ever since." A full account of the case was published in *The Sacred Union*, Arlington, N. J., April 26, 1886.

Dr. Charles H. Shepard, of Brooklyn, reported the following case to the American Medical Association, at a meeting held June 1–4, 1897: "Dr. M. H. Hermance, of Brooklyn, saved a boy from the agonizing death of hydrophobia by the use of the vapor bath, which was applied while the patient was tied down to the bed. In about three-quarters of an hour after beginning operations a profuse perspiration was induced. When he began to sweat freely signs of returning consciousness appeared, which increased as the perspiration was continued, until in the space of about two and a half hours he was fully restored to consciousness, with a perfect relief from all his hydrophobic symptoms, the pain in the bitten hand and arm included, of which he had complained very much in the intervals of consciousness between his convulsions."

Dr. L. P. Haskell, of Chicago, reports the two following cures of hydrophobia, which he witnessed at the sanatorium of the late Dr. M. P. Hanson, of Milwaukee. He says: "I had opportunity to see much of Dr. Hanson's operations and the great success he attained. His son owned a dog which was attacked with all the symptoms of hydrophobia. His paroxysms were violent. He was secured at the end of a pole by a lasso and taken into the hot-air room (175 F.). After raving a while he quieted down, went to sleep, and was cured. I saw him three years later. About a year after this cure a man, living in a Wisconsin town, and his horse were bitten by a mad dog. The horse soon after died in great agony. Then the symptoms were manifested in the man, and a friend who knew of Dr. Hanson's experiment with the dog took the man to the sanatorium, and he was cured."

Dr. P. Canitz, of New York City, testifies to having cured five cases of hydrophobia by means of the Buisson bath. The disease, in three of these cases, had advanced to a stage ordinarily pronounced hopeless. Convulsions had become so violent that the patients had to be strapped to their beds, and in one case, in which treatment was delayed until after the fourth day of the attack, the patient was in the extreme horrors of rapidly approaching death. In all these cases the aggravated symptoms subsided during either the first or second application of the treatment, and after four or six days all signs of the disease had disappeared. Strapped to a steam lounge these patients were subjected to steam and hot dry air—the temperature being gradually increased until 140° F. was reached; then, still sweating profusely, they were wrapped in cold wet sheets (wrung dry) and swathed in blankets, with hot-water bottles applied to the feet, calves, and thighs, and allowed thus to remain from one to two hours, when a tepid bath (90° or 92° F.) was given, followed by a cold spray douche. The sweating process was repeated daily and the full pack twice daily up to the period of convalescence, and the treatment in a milder form continued for several days subsequently so as to insure complete success. In no instance was there a relapse.

The frequency of the bath must depend upon the severity of the symptoms; and the maximum rate of temperature must be regulated according to the facility with which the patient perspires. The head must be kept cool with cold applications and the patient freely supplied with cold water to drink, avoiding all alcoholic stimulants and adhering to a light, farinaceous diet. If the patient is subjected to a bath on the first day of hydrophobic symptoms, probably the first bath would prevent its development, but even after the patient is apparently well the sweating process should be continued daily until all danger of recurrence is past.

"The efficacy of the Buisson treatment for hydrophobia is testified to," says the London *Star*, May 3, 1898, "in a letter from B. K. Illava, district Abkari, inspector of the Bassein district, written to Mr. Malabari, of Bandora. It says: 'It affords me great pleasure to note the result and let you know the genuine efficacy of the Buisson bath you were kind enough to get me a loan of from Dr. de Monte, of Bandora, to be used for my uncle, Mr. Jehangir H. Kotwal, as he was bitten by his own bulldog that had gone rabid. If it were not for your kind advice and prompt loan of the bath he would have been a positive victim to the fell disease, as two cows, one dog, one Hindoo woman, by name Gungabai, aged forty, and a boy of ten years of age, who were all bitten by the same dog, died at different periods, all showing symptoms of hydrophobia.' Why be Pasteured and run increased risk of death?"

On May 6, 1895, Dr. Ganguli, of Dinageyur, India, treated four persons bitten by a rabid jackal on the 29th day of April, 1895. All these four are now in perfect health. One man, who was bitten by the same animal, and did not undergo the Buisson treatment, died of hydrophobia. A Mohammedan, bitten by a rabid dog March 22, 1896, and treated by Dr. Dass, of Naraenganj, India, fifteen days afterward, is now in perfect health. Eight persons who were bitten by the same rabid dog and did not undergo the Buisson treatment, died of hydrophobia. A Hindoo bitten by a rabid dog on April 2, 1896, treated by Dr. Dass twenty-two days after the bite, is now in perfect health. Three persons who were bitten by the same rabid dog and did not undergo the vapor-bath treatment, died of hydrophobia.

William Tebb, Esq., of Rede Hall, Burstow, Surrey, England, writes from Bombay on March 21, 1896:

"At Lucknow there is an encouraging report of the success of the Buisson system in preventing hydrophobia in several patients who had been bitten by mad dogs—while one unfortunate man bitten by one of the same dogs (who refused the treatment) died of hydrophobia. At Allahabad, the superintendent of the government hospital said that five persons had been bitten by a mad dog, four of whom were treated by him with the vapor bath, and no harm followed; the fifth refused the bath and died of hydrophobia."

It is very clear from the symptoms that in hydrophobia the nerve centres are in a state of excitement; it is also very evident from some of the symptoms that there is excess of circulation of blood within the brain and nerve centres. It has been demonstrated to me long since that by methods which withdraw excess of blood in active circulation from the brain and nerve

centres, in nervous diseases as well as in those like delirium tremens, and the blood poisoning in the coma of Bright's disease, due to a poison absorbed, the conditions treated will rapidly be subdued. Pathological investigation also demonstrates excess of blood within the brain and nerve centres, and the results of the treatment, as we see, prove that by flushing the sweat glands with blood hydrophobia may be cured, even in the advanced stages.

A very sensible statement by a contemporary writer illustrates the effect upon internal congestions of this method, and why they are relieved:

"Very few people comprehend why the hot-air bath is so potent in the cure of disease. The reason is simple, and readily understood. Nature's method of protecting the body from the effects of heat, especially high temperatures, is by the evaporation of moisture from the surface of the body, and this moisture is provided by the perspiration, and the less clothing the more effectual the results, so that natives of hot climates who are nearly naked realize more fully the benefits of perspiration. Upon submitting one's body, divested of clothing, to the 150° F. and upward of heat, demand comes for relief; soon the pores are opened, perhaps to an extent not before realized for months or even years, as many persons have inactive skins, and when this is the case other organs, and notably the kidneys, must take on double duty, and are thus overtaxed and diseased. So now the pores are actively at work, and the poisonous, worn-out material is being eliminated from the body through nature's sewerage system—the pores. What follows as a sequence? Why, *as the blood furnishes the perspiration, it necessarily comes to the surface, and thus the circulation is equalized over the entire surface, and as the logical sequence of this all congestive tendency is relieved, thus establishing perfect equilibrium, which is absolutely essential to perfect health*" (Italics mine).

## Progress of Medical Science.

**Eczema Treated by X-Rays.**—Holland (*British Medical Journal*, April 29, 1899, p. 1024) records the case of a woman, nineteen years old, who presented a chronic eczematous eruption covering the dorsum of one hand, following the evacuation of an abscess that had formed over a metacarpal bone. The skin was thickened, scaly, and cracked, and the seat of a number of adherent blackened scabs. After seven exposures at intervals of four or five days to the action of an *x*-ray tube at a distance of from four to seven inches and for periods of fifteen minutes, the eczema had disappeared and the hand was well. The result is attributed to the stimulating influence of the *x*-rays.

**In the Treatment of Dysentery with Ipecac** Dalgetty (*British Medical Journal*, April 15, 1899, p. 903) pursues the following plan of procedure: A large mustard plaster is applied over the stomach and 20 minims of tincture of opium are given, followed in ten minutes by gr. xl. of powdered ipecacuanha in four ten-grain pills freshly made up. The horizontal position is to be maintained for four hours, no food or drink being allowed during this time. The treatment is to be repeated in eight hours if no improvement has taken place; otherwise, smaller does are employed with the same precautions.

**Strontium Bromide in the Treatment of Epilepsy.**—Upon the basis of a not inconsiderable experience Roche (*Lancet*, April 22, 1899, p. 1089) renews an earlier recommendation of strontium bromide in the treatment of epilepsy. Two unequal doses should be given daily, the larger half an hour before the time of day that the attacks are most frequent, and the smaller twelve hours later. A drachm a day is a good initial dose, in two parts of gr. xl. and gr. xx. respectively. Larger doses may be given without causing toxic manifestations. Sufficient, however, should be employed to control the attacks. When an aura is present gr. xx. additional are administered every half-hour until the sensation passes off. Arsenical solution is given when acne appears. Animal food is restricted; stimulants are interdicted, an open-air life is recommended. The treatment should be continued for an indefinite length of time.

**Carbolic Acid in the Treatment of Influenza.**—Wiglesworth (*Lancet*, April 8, 1899, p. 959) recommends, upon the basis of personal experience, the employment of carbolic acid in doses of from gr. vii. to viii. every two hours in the treatment of influenza. In one case gr. xix. of the drug were ingested without deleterious effects.

**Mosquitoes and Malaria.**—In the *Annales de l'Institut Pasteur* for February, 1899, Ronal Ross, of the Indian military service of Calcutta, presents the results of a lengthy series of examinations on this question. He states that the plasmodium may be found in the stomach of the mosquito; that it can grow there and can develop what have been called spore-threads. These may also be found in the poison sac of the mosquito, and from this may be conveyed to man in the sting. He thinks he has been able to follow the cycle throughout its various stages. He has been unable to show, by any yet developed technical procedures, the spore-threads in the poison sac, nor has he been able to make preparations which definitely stain the plasmodia in the mosquito's body. He further states that the parasite of Texas fever and other fevers of Africa and other countries may be conveyed by other insects.

**Aspidium Spinulosum as an Anthelmintic.**—Aspidium spinulosum, which is one of the most common of the ferns of that region, has recently been examined by Walter Lauren, of the Pharmacological Institute of Helsingfors. Some years ago Flückiger, of Bern, showed that it contained resin glands, and Poulson obtained from it, by micro-chemical analysis, filicic acid. The author prepared a ten-per-cent. ethereal extract, and having found eggs of the Bothriocephalus in his own dejecta took 4 gm. of the extract prepared by himself. This he followed by ol. ricini, in about two hours. Two hours later he passed a Bothriocephalus latus, eight metres long, with its head entire. Investigations on others confirmed his results. The extract is best given in capsules, keratin-coated or hardened in formalin.—*Therapeutische Monatshefte*, April 13, 1899, p. 211.

[Since the official Aspidium (Dryopteris filix mas) is rare in this country, and the D. spinulosum is extremely common, more common even in the eastern States than D. marginalis, its inclusion in the next pharmacopœial revision might well be considered.—Ed.]

**Methyl Salicylate in Acute Rheumatism.**—The disagreeable taste, the disturbance of the stomach and intestines, and the poisonous effects of salicylic acid make a triad of effects which render this drug many times inadvisable in the treatment of articular rheumatism. The wide use of the oil of wintergreen in this country has led Dr. E. Schmoll (*Correspondenzblatt für Schweizer Aerzte*, 1899, No. 3) to use methyl salicylate by inunction. The investigations of Lannoir and Linossier have shown that it can be locally absorbed The author's results were assur-

ing in some twenty cases treated. The drug appeared as the sodium salt in the urine in from one and one-half to two hours, and the beneficial effects were noted as early as one and one-half hours after inunction, though the usual time for complete action was from five to six hours. Doses of from 2 to 6 gm. were employed with no untoward after-effects. He believes that the treatment by this method is contraindicated only on the first day of the acute stage of the disease. In subacute and chronic cases and in muscular pains of obscure origin, sciatica, and lumbago the drug is indicated.

**On Menstruation and Ovulation in Monkeys and in the Human Female.**—Dr. Walter Heape, of Trinity College, Cambridge (*British Medical Journal*, December 24, 1898), writes as follows: "A review of the various modern views of menstruation in the human female leads to the opinion that it will be found that while the histological phenomena accompanying menstruation in the latter may differ somewhat in detail from those in monkeys, they are practically identical processes; further, menstruation and 'heat' are very much more similar than has hitherto been recognized. With regard to the relation of ovulation to menstruation, if it is granted that menstruation in monkeys is the same process as menstruation in woman, then it can definitely be stated that ovulation does not occur during each menstrual period, and that it does not necessarily occur during any menstrual period. I have shown that menstruation frequently occurs without ovulation—probably this is the case during the whole of the non-breeding season; while Leopold and Miranoff have shown that ovulation may occur independently of menstruation in the breeding human female. The want of power to ovulate is no doubt one of the causes of sterility, and the importance of all considerations dealing with the process of ovulation is obvious to those who have to combat sterility. It is a fuller knowledge of the cause of ovulation which is required, and it is hoped it will be forthcoming and be found of assistance to those who desire to induce ovulation."

**Stigmata of Syphilis in Children.**—In a paper on the above subject read before the New York Academy of Medicine, March 2, 1899, Dr. R. H. M. Dawbarn enumerated some twenty-seven stigmata of syphilis, that aid in making an early diagnosis:

(1) The description given by Diday. The syphilitic child is wrinkled and drawn in features, with a yellowish-brown *café-au-lait* color, though with it all the child may not be poorly nourished, but on the contrary may be plump and rounded. (2) Thick umbilical cord, often over-long and slow to fall, leaving the child liable for a longer time than usual to septic infection through the navel. (3) Pemphigus, consisting of bullæ and blebs, at times invading the palms and soles, consisting usually of lesions vesicular in character, which may be small, discrete elevations, but sometimes large and confluent. (4) Erythema-syphilitic roseola, invading first usually the lower abdomen, coming on commonly about the third week; then the copper-colored patches, syphilitic pennies, as they have been called, though syphilitic farthing-pieces would be a better name. They are oftenest about the size of the baby's finger-nails. Cutaneous syphilides, however, occur in only twenty-five per cent. of the cases of congenital syphilis. (5) Condylomata. (6) Coryza. An attack of snuffles is always suspicious in the new-born; when it persists it is almost pathognomonic. A well-known woman novelist has given great publicity to the phrase "a little old man with a cold in his head," so picturesquely descriptive of the syphilitic child. (7) Laryngeal symptoms, especially a hoarse cry. (8) Mucous patches. (9) Stomatitis, especially when it becomes generalized. Holt considers a general stomatitis as a constant symptom of congenital syphilis. (10) Do not be deceived into a false sense of security as to syphilis by the absence of enlarged glands. Lymph-nodular enlargement is usually absent in congenital syphilis. (11) Hemorrhages, subcutaneous or from mucous membranes. (12) White pneumonia, though this is a post-mortem sign, and the specific nature of the pneumonia can only be suspected during life. (13) Hepatic enlargement but without jaundice. (14) The spleen is enlarged in over half the cases. It has been known to reach four times its normal size in three weeks. (15) The ground-glass cornea is pathognomonic. Other eye lesions occur, as iritis, but the keratitis is of most value. (16) Middle-ear disease. It is to be remembered that the Hutchinson triad of symptoms is the notched teeth, the specific keratitis and deafness, or middle-ear symptoms without known cause. (17) Alopecia, so that the infant looks like a badly plucked fowl. (18) Orchitis. (19) Neuroses, especially epilepsy and any and all forms of palsy. (20) Bone lesions—the first and most important, the syphilitic osteochondritis of the epiphyses. The child's bones are sore. It is tender when handled. Later rickets not infrequently develops. (21) Syphilitic periostitis, the syphilitic nodes of Parrott. (22) Syphilitic dactylitis. (23) Peculiar onychia. (24) The teeth come early and decay easily and soon. It used to be said that it was unlucky for a child to be born with teeth. (25) The Hutchinson teeth. In the permanent set of teeth the upper central incisors are pegged, apt to be separated, and are notched, the enamel having disappeared from the central portion of the cutting edge. (26) Irregularities and asymmetry in the bony skeleton. (27) Other enduring stigmata are: bosses on the skull, nodes on the long bones; chronic fissures of the corners of the mouth, or the whitish contracted cicatrices they leave after them; scars on the upper third of the legs; the remains of ulcers are especially significant if symmetrical.—*Medical News.*

**The Serum Reaction of Typhoid Fever.**—The fact that the reaction is usually absent during the earliest days of the disease has led many to the conclusion that its value is slight, since it is only in the earliest days of the disease that the diagnosis is difficult. But in answer to this it should be stated: (1) That the reaction usually is present when the patient first consults the physician, not when he begins to feel poorly. In most parts of the country typhoid is chiefly the disease of the less-educated classes, and hence little attention is paid to the earliest symptoms, and almost all cases are "walking typhoids" in the sense that they keep about for a day or two after they begin to have fever. Over ninety per cent. of the cases seen at the Massachusetts General Hospital since 1896 have shown the typical reaction at the time of entrance. (2) But even when the reaction does not appear until the second week or later, it is of the greatest diagnostic value in many cases—especially: (*a*) in the diagnosis of abortive or atypical cases; (*b*) in the differential diagnosis between typhoid and typhus, malaria, remittent, dengue, Malta fever, yellow fever, and other infections of tropical or semi-tropical countries; (*c*) in the identification of obscure forms of tuberculosis or deep-seated suppurative processes; (*d*) in the differentiation of typhoid from pneumonia and influenza; (*e*) in the retrospective diagnosis of typhoid. This last application of the serum test is of value not only for diagnosis, prognosis, and treatment, but in the investigation of epidemics and from various medico-legal standpoints.—Dr. Richard C. Cabot, "The Serum Diagnosis of Diseases," p. 81.

# MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM WOOD & CO., 51 Fifth Avenue.

New York, July 22, 1899.

## HOW SHALL THE DISPENSARY LAW BE ENFORCED?

THE special committee appointed by the State board of charities to prepare a form of license to be issued to dispensaries under the new State law has very wisely formulated inquiries to be answered by the managers of dispensaries in order that a consensus of opinion may be obtained as to the proper basis for action in the premises.

On a previous occasion, while commenting upon the provisions of the law in question, we had every reason for believing that they were of a character and scope to meet all necessary requirements, the main difficulty being in formulating such well-understood rules as should give them a thoroughly practical application. Now when opportunities are offered for securing the latter end it is to be hoped that all parties interested in the necessary reforms of medical charity will lend a helping hand to the committee and freely offer suggestions accordingly. Fortunately the explicit wording of the law leaves no doubt concerning its general purpose and its broad intention. It is only in matters of detail that any suggestions are solicited.

The first question regarding the requirements to be attached to each application for a license could seemingly be answered very satisfactorily by simple reference to the legal provisions to that end. Although from the standpoint of strict interpretations of the letter of the law there may be some differences of opinion, it will be comparatively easy for any conscientious board of managers to work harmoniously with the committee in preventing or suppressing obvious fraud.

The fundamental principle which should govern all decisions on minor points should rest upon the simple and well-understood assumption that medical charity is intended for the really poor, and for such only. It will be only with such institutions as are disposed to dodge the real issues in the case that there can be any possible trouble.

On the basis of common honesty of intention the public has the right and privilege of expecting more from a board of respectable and responsible citizens than from the ordinary dispensary patient, who when not really deserving will cheat whenever he can. Hence the second and third questions of the committee covering necessary rules for applicants for medical relief may be somewhat more difficult to answer than the first.

It may be easy to insist that only the deserving poor shall receive free medical treatment, but very difficult to guard against the fraudulent representations of the majority of applicants. These have been the difficult problems to solve from the very beginning of charitable work, and have afforded all sorts of opportunities for excusing every form of fraudulent pretension on the basis of the impossibility of offsetting it.

One reason for this was that there was no common ground of agreement between the dispensaries to act in concert against the monstrous evil. Now, however, there appears to be a chance for striking solid bottom on a level of common interest, and we may have hopes of reforms accordingly.

Everything must depend obviously on uniformity of system, and this is fortunately quite possible of attainment, if indeed it is not obligatory on the part of the State board having such regulations in charge. The whole responsibility of properly discharging the real duty of charity rests upon the dispensary managers. Obviously they must decide on the merits of all claimants. It is no longer a question of lack of power to do so. Any safeguard to the desired end can now be insisted upon with a sufficiently comprehensive law to enforce adopted regulations.

The pivotal point around which all real reform must revolve is the absolute abolishment of indiscriminate charity. The proof of worthiness must come from the applicant. This can be so easily obtained in the proper way that no one need suffer as the result of the most stringent safeguards. It is plainly to be seen as the result of long experience that the matter of deciding upon the merits of applicants should not rest with the examining physician. All his time should be occupied in the treatment of patients sent to him. The work of selection of persons entitled to free treatment should be left to some officer of the institution appointed for that special purpose and well acquainted with necessary detail work associated with his duties. He should preserve a list of all applicants and furnish a copy of the same to all other institutions of his class, so that all should have a proper basis of action against unworthy patients. By such a combination of interests the most accurate information can be obtained at a comparatively small cost and be a common stock of knowledge for all.

More than this, it would seem to be eminently judicious to adopt some form of certification for applicants by which each and every one should be suitably recommended by some proper sponsor. Except in cases of sudden accident or other emergency when there is no time to ask questions, there is no good reason why every applicant for relief could not in some way obtain proper credentials. A physician, clergyman, judge, or any other reputable citizen would answer every purpose. Whatever may be urged on theoretical grounds against the practicability of the scheme, it is safe to say that if some such preliminaries were made obligatory the institutions could

very consistently enforce them, and the applicants would quickly find the way of complying with them. But whatever suggestions may be made to the committee, and whatever may be the outcome of the prospective interchange of views, we shall await the ultimate conclusions with becoming concern

## THE FUNCTION OF THE SUPRARENAL GLAND.

The function of the so-called ductless glands has always been a matter of much interest as well as of obscurity, and it has of late been made a subject of considerable investigation. Of that of the suprarenal gland comparatively little is known, although it is believed that it has something to do with the disintegration of red blood corpuscles or the removal from the blood of the products of such disintegration. In a pathological way little more is known concerning the suprarenal gland than that its disease, and especially tuberculosis, is sometimes attended with the symptom complex of Addison's disease.

Physiological investigation of the action of extracts of the suprarenal gland shows that they have the power of increasing blood pressure, and it has been further shown that this property resides in substances contained in the medullary portion of the gland. Auld (*British Medical Journal*, June 3, 1899) has found that when an aqueous extract of suprarenal medulla is injected into a vein that has been clamped as high up as practicable, a marked diminution of pressure is recorded on releasing the vein after a few minutes, as compared with that produced by an injection into a free vein, and he concludes, therefore, that the pressure-raising substance undergoes a process of destruction in the blood. Further experiment by the same investigator shows that cats from which one suprarenal gland is removed survive, but die when the second is removed also or is destroyed, even when a long period elapses between the two operations. After the second operation the animal lies on its side in a state of intense weakness, has a peculiar drowsy look, and refuses to move. In one case, death was preceded by convulsions. On post-mortem examination no hypertrophy of the remaining gland was found when one alone was removed. On the other hand, the thymus gland was greatly hypertrophied and the spleen considerably enlarged. It is suggested that the hypertrophy of the thymus may be compensatory for the loss of the suprarenal, both structurally and functionally; while the enlargement of the spleen may be indicative of increased hæmolytic action.

The active principle in the medulla of the suprarenal gland is scarcely to be looked upon as a normal secretion, whose withdrawal can be made responsible for the symptoms attending removal of the gland on each side. These symptoms, however, suggest the rapid accumulation in the system of a toxic substance that is not likely to exist in the blood as a vaso-constrictor, but as a result of the decomposition of which by the suprarenal gland a vaso-constricting substance may be formed. The pigmentation of Addison's disease and the chromogenic properties of the suprarenal point to a constituent of (effete) hæmoglobin as the toxic agent. The conclusion is reached that the function of the suprarenal consists, in part at least, in destroying deleterious substances and also in furnishing certain substances to the blood. As the work seems to be done by the medulla, there is ground for regarding the vaso-constricting substance as evidence of the former function. Finally, the employment of thymus feeding is suggested in the treatment of Addison's disease.

## THE ACTION OF ALCOHOL.

Professor Attwater, of Wesleyan University, who has recently conducted a series of experiments to determine the effects of alcohol on the human system, has reached the conclusion previously held by all but the most rabid and unscientific prohibition advocates, that alcohol taken in small and digestible amounts is a food. The experiments were mainly undertaken with a view to determine the nutritive value of alcohol. This substance was given in various forms, and pure alcohol was also administered with water or coffee. It was taken with meals. It was found that alcohol is oxidized in the same manner as any other food materials, and is transformed into heat and muscular energy. Unlike, however, the fats, starch, and sugar, it does not form tissue, but gives forth energy. The experiments were not conducted for a sufficiently long period to demonstrate what the effects upon the human organism might be of the habitual use of alcohol, yet many writers in the daily press have assumed that they have proved the innocuousness of alcohol as a beverage. This is, of course, far from being the case, and the promulgation of any such belief would be nearly as injurious as is the other more familiar extreme advocated so strenuously by intemperate prohibition orators.

## FEVER FIGHTING.

With the return to Santiago of Dr. General Leonard Wood after so brief a vacation period there goes the sustaining sympathy of the country's entire medical profession. The physician no less than the soldier knows what it means to be called upon for a new duty requiring sustained effort before natural recuperation from the last endeavor has taken place.

General Wood, combining in his personality the attributes of a brave soldier and a true physician, is not only doubly equipped to fight the yellow fever as he formerly fought a human foe, but he can the better respond to duty's call without a murmur of complaint or thought of selfish inclinations. We should not for a moment forget the vast importance to this country of the battle now being carried on against dirt, disease, and death. The constant menace of years to this whole country, but especially to our Southern States, must in the nature of things require long-continued effort to overcome. The material in the man's composition which permitted him to do what he did

to the Apaches in Arizona, to the Spaniards at La Quasima, and to the starving Cubans at Santiago will enable him to cope successfully with Yellow Jack at the present time.

A man who in a few short months can make a comparatively clean city out of a pest-hole, reducing the mortality from two hundred a day down to ten; a man who can overcome the prejudices of age and instill the elements of hygiene into minds where no suspicion of it ever lurked before; a man who at the same time can establish such radical reforms in all branches of public service as Dr. Wood has done in Santiago is the man the country wants there now to fight the fever, and we can but express our regret that the anticipated vacation and change of scene should have been so rudely interrupted.

## News of the Week.

**Philadelphia Hospital.** — Dr. Henry W. Cattell has been elected pathologist in succession to Dr. John Guiteras, resigned.

**The Alvarenga Prize** of the College of Physicians of Philadelphia has been awarded to Dr. Robert L. Randolph, of Baltimore, for his essay entitled "The Regeneration of the Crystalline Lens; An Experimental Study."

**The Cumberland County (N. J.) Medical Society** convened at the Doughty House, Millville, July 11, 1899, with Dr. Ellsmore Stites presiding. Dr. G. E. Day read a paper on "Rational Therapeutics." Several interesting cases of eye strain were also reported by him.

**To Prevent the Spread of Contagious Diseases,** the Pennsylvania State board of health has adopted a regulation requiring teachers in schools whose boards act also as boards of health to report immediately to the secretaries of such boards or to the agents designated by them all cases of contagious diseases occurring in their respective schools.

**Tuberculosis in Baltimore.**—The health commissioner of Baltimore, Dr. C. Hampson Jones, has just prepared a map of that city showing the sections in which deaths from tuberculosis occurred during 1898. The largest number was naturally in the more crowded districts, and many of the victims were negroes, but the few cases in the better portions of the city were partially accounted for by the fact that patients of the wealthier class generally seek a milder climate and die away from home.

**The French Association for the Advancement of Science.**—The next meeting of this association will be held at Boulogne-sur-Mer, on September 14–21, 1899. On this occasion a statue of Duchenne de Boulogne will be dedicated. A new sub-section on medical electricity has been created, and its first sessions will be signalized by discussions on "Electrolysis in the Treatment of Stricture," "Radioscopy and Stereoscopic Radiography," "Recent Progress in Radiography," and "Technique and Results of Endodiascopy." The chairman of this sub-section is Dr. J. Bergonié, of Bordeaux.

**The London Polyclinic** recently opened appears to offer to physicians going abroad for study that concentration of instruction which has always been so notably lacking in the great English metropolis.

**For the Protection of the Water Supply.**—In accordance with an act passed by the last legislature for the prevention of the pollution of water supplies of cities of the first class, the Pennsylvania State board of health has adopted a regulation forbidding the pollution of the Schuylkill River by deposits of excrements, whether from houses, manufactories, or boats.

**The Death of the Tsesarevitch.**—The Grand Duke George, of Russia, whose death was announced last week, succumbed to hæmoptysis coming on during a bicycle ride. He was alone, and had been riding very rapidly, when he suddenly began to spit blood. He alighted from his wheel and died almost immediately, while a peasant woman, the only person near at the time, was bathing his mouth and temples with cool water.

**Time and Temperature.**—A Massachusetts physician recently in this city for a few days' sight-seeing was waylaid and deprived of his valuables, including a gold watch. The thieves left the doctor's thermometer, which the morning papers said was because it was "chained to the vest." We presume the unfortunate physician is now measuring his patients' fever more accurately than ever, while guessing at the pulse-rate, and possessing his soul in patience with the thought that those who take time in the here are apt to do time in the hereafter.

**The Lying-In Hospital.**—The plans of the new building to be erected by Mr. J. P. Morgan for the Lying-In Hospital provide for a terra-cotta, brick, and limestone structure with a steel frame, nine stories in height. The building will occupy the west side of Second Avenue from Seventeenth to Eighteenth Street, fronting one hundred and eighty-four feet on the avenue, eighty-two feet on Seventeenth Street, and one hundred and sixty-five feet on Eighteenth Street. The main entrance will be on the avenue side. The lower part will be built of limestone, and the superstructure of brick with terra-cotta facings.

**The Cultivation of the Bacillus Lepræ.**—At a recent meeting of the National Academy of Medicine of Bogota, Dr. Carrasquilla asserted that he had successfully cultivated the bacillus lepræ on sloped solidified human serum and on beef bouillon prepared according to the method of Thoinot and Masselin. The bacillus was then cultivated from serum to serum, and from bouillon to bouillon, pure cultures being always obtained. Dr. Carrasquilla further states that he observed the bacillus in motion in two stages of its development—as long, slender bacilli, which move in an undulatory manner; and as short, coarse, almost ellip-

tical bodies moving rapidly in a straight line. In the latter he fancies he has observed flagella, but he is not positive as to this. His results do not entirely accord with those obtained by Professor Spronck, of Utrecht, who has also claimed to have cultivated Hansen's bacillus. Professor Campana, of Rome, has also convinced himself that he has successfully cultivated the bacillus lepræ. These experiments require confirmation and extended observation before they can be accepted as absolute.—*British Medical Journal.*

**An Epidemic of Tetanus** has followed the noisy demonstrations on Independence Day, and we may once more ask ourselves if the Chinese method is the best one for the celebration of our national holiday. The Chicago *Tribune* has published figures gathered from correspondents throughout the country, showing a loss of one hundred and forty-one lives as a result of the last Fourth-of-July celebration. Some of these died on July 4th, and the others from injuries received then. Tetanus caused the death of eighty-three out of the one hundred and forty-one. Twenty-six deaths from tetanus occurred in this city and its immediate environs during two weeks following the Fourth. The serum treatment has had a quite extensive trial and appears to have been rather unsatisfactory in its results. It will not improbably be found that Baccelli's carbolic-acid treatment is more reliable and productive of better results than orrhotherapy as at present employed.

**The Hospital Ship "Relief"** is expected shortly in San Francisco with about two hundred and fifty sick soldiers from Manila. She was considerably delayed off the China coast by a succession of heavy storms.

**Special Allowance for Sick Soldiers.**—In an order recently issued by the War Department special provision is made for soldiers sick in hospital by the allowance of forty cents a day a man for the purchase of delicacies and extra diet.

**Sneak Thieves in a Hospital.**—Two sneak thieves entered the Monmouth Memorial Hospital one day last week and succeeded in carrying off money and gold watches and rings worth several hundred dollars. The men told the matron that they had been sent there to put up gas fixtures, and while the matron and the nurses were at lunch the men ransacked their rooms and escaped.

**A Corps of Female Army Nurses.**—An order has been issued for the organization of an army nurse corps, under the direction of the surgeon-general. The corps will be under the immediate supervision of Dr. Anita McGee. It will consist of chief nurses, nurses, and reserve nurses. The surgeon-general may assign female nurses to duty at all army hospitals where the cases treated require the care of trained nurses. Contracts for nurses will be for one year, except for immune nurses, who will not be required to sign for any definite period. For service in the United States a nurse will receive $40 per month, and in any of the colonies $50. Chief nurses over from five to ten nurses will receive $10 additional, and those over ten or more nurses $25 additional. In case a nurse becomes ill while in the service, medical attendance and care will be furnished, but extra leave, with pay, will not be allowed.

**A Protest Against Christian Science.**—A meeting was held in this city on Thursday evening of last week, at the instance of the Medical and Legal Relief Society, to discuss plans for the abatement of the abuse of Christian Science. The draft of a proposed bill was presented, the bill providing that any person advising another person not to call a doctor or surgeon in case of illness or injury should be deemed guilty of a misdemeanor, and, if the illness or injury resulted in death, of manslaughter. There were members of the sect present, and they seized upon the opportunity thus presented of expounding their tenets and reviling all sane objectors. The proposed bill was faulty in many respects, and the meeting adjourned without recommending that it be enacted. The chairman announced that he would appoint a committee to consider the bill.

**The Yellow Fever in Santiago** is believed to have been stamped out, no new cases in the city or camps having been reported at present writing, for several days. The last case was that of a hospital nurse who was supposed to be an immune. General Wood announces the end of the epidemic, but has ordered that the troops be kept in the mountains until the end of the rainy season in November.

**Dr. A. Jacobi,** of this city, has been made an honorary president of the thirteenth International Medical Congress, to be held in Paris in the summer of 1900. It is gratifying to learn that an American has been selected among those to be honored in this way, and upon no one could the honor be more fittingly bestowed than upon Dr. Jacobi, who has in many of these international gatherings done so much to promote the interests and widen the fame of American medicine.

**The Plague** is still raging in Hong Kong, there being from twenty-five to thirty deaths a day and nearly double that number of new cases. The disease is confined to the Chinese part of the city, no Europeans having been attacked. The sensational papers here are making the most of an alleged alarmist article in the *British Medical Journal* predicting an invasion of Europe and America by the disease, and urging the sending of an international commission to avert the evil. There is undoubtedly some danger that the plague may invade certain countries of Europe, such as Turkey and Spain, where cleanliness and sanitation are but little practised, but the fact that cleanly Europeans in the East so seldom fall victims would indicate that there is little cause to apprehend an epidemic of the disease in any civilized region of Europe or America. A correspondent of the *Evening Post* states that great interest has been aroused by the extended tests to which Dr. Haffkine's plague prophylactic is to be put. Captain Leumann, of the Indian medical service, who has been lent to the government of Natal

to introduce inoculations there, has taken fifty thousand doses with him. Lieutenant Stephens has been lent to the government of Mauritius, and has taken twenty thousand doses. At the request of the Chamber of Mines of Johannesb rg, ten thousand doses have been sent there. The consul-general at Zanzibar has applied for ten thousand doses, the crown agents of the Gold Coast Colony for three thousand, and one thousand have been sent to the Russian governor at Nicosia. The Italian government has applied for small quantities, and a supply also has been sent on private demand to Hong Kong.

**University of Pennsylvania.**—The faculty of the University of Pennsylvania has recommended the election of Dr. James Tyson as professor of medicine, of Drs. John H. Musser and Alfred Stengel as professors of clinical medicine, of Drs. Judson Daland, M. Howard Fussell, John K. Mitchell, and F. A. Packard as assistant professors of medicine, and Dr. Gwilym G. Davis as assistant professor of applied anatomy.

**Instruction in Diseases of the Nervous System in London.**—American physicians visiting London during the autumn are often disappointed at finding most of the better known physicians away from town, and the various clinics either closed or left in the hands of younger men. The staff of the West End Hospital for Diseases of the Nervous System, 73 Welbeck Street, have therefore decided to give a short course of clinical demonstrations for practitioners visiting London during a part of August and September. These will be given each Tuesday and Friday afternoon, commencing August 18th.

**Infant Mortality.**—In a recent report, Dr. S. W. Abbott, of the Massachusetts board of health, says that, while very marked improvement has taken place, in Massachusetts, in most directions as a result of sanitary work on the part of the health authorities, very little progress appears to have been made in limiting the death rate of infants. Beyond all question, he thinks, the most important factor in diminishing the infantile death rate lies in the direction of the food supply. "Further improvement of the milk supply of our cities is needed; the co-operation of women's sanitary associations, whose organizations should be encouraged; the intimate control by boards of health of the methods of feeding among the laboring classes; the establishment of day nurseries, or crêches, in manufacturing cities, under careful sanitary control, and the circulation of literature generally aimed at improvement in this line of sanitary work."

**Prize Essay on the Tropical Army Ration.**—Appreciative of the necessity for proper food for the men of the army and navy serving in tropical climates, Dr. Louis L. Seaman, late major-surgeon First Regiment United States volunteer engineers, has offered through "The Military Service Institution of the United States" the sum of $100 in gold (or a medal of that value as the successful competitor may elect) for the best thesis on "The Ideal Ration for an Army in the Tropics." This competition is open to all commissioned medical officers of the army and navy (volunteer or regular). The executive council of the Military Service Institution, at its meeting of the 14th inst. at Governor's, Island, adopted a resolution of thanks to Dr. Seaman for his handsome offer, and decided that all papers on this subject should be submitted by March 1, 1900, and that Colonel Weston, acting commissary-general, Lieut.-Col. Charles Smart, deputy surgeon-general, and Lieut.-Col. William E. Dougherty, Seventh United States Infantry, be requested to act as the board of award.

**Dr. Charles Lewis Allen**, of Washington, D. C., has been appointed pathologist and second assistant physician at the New Jersey State Hospital at Trenton.

**Medical-License Decision.**—The Dauphin County (Pa.) court has declined the request of Dr. George W. Ludwig, of Chambersburg, to mandamus the State Medical Council to issue a license to him to practise medicine in the State of Pennsylvania on the ground that a license obtained in the State of Maryland gives him this authority. The Medical Council having stated under oath that the medical law of the State of Maryland fails to meet the demands of the medical law of Pennsylvania, and that its requirements for licensure are not substantially the same, the court held that the council is by act clothed with discretion in the premises, and the rule was discharged.

**A City Hospital for Norfolk.**—A correspondent writes that probably no city of its size in the South needs a city hospital as badly as does Norfolk. Two hospitals exist there now, but the Protestant hospital being inaccessible, necessity compels the drift of patients to the other.

**The Colorado Medical-Practice Bill,** known as the Cannon bill, passed both houses of the legislature by a good majority, but was vetoed by the governor on the ground that "medicine is not a science which has reached perfection, but merely a series of experiments." The proposed law was not a very stringent one, but still called for an examination as a test of fitness.

**Validity of a Legacy to a Physician.**—A decision has recently been rendered by the surrogate of Rensselaer County, in this State, whereby a physician's wife was debarred from receiving a legacy from one of her husband's patients. This patient, a man eighty years of age, while in his last illness revoked a will leaving his property to a sister who had lived with and attended him, and made a new one devising nearly the whole of his estate to the wife of his attending physician. The will was contested by the legal heirs, and the surrogate revoked the probate of the will, holding that there being no sufficient explanation of the man's action in revoking his former will and devising his property to one who was no relative and a comparative stranger, the presumption remained that undue influence had been exerted by the attending physician.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending

July 15, 1899. July 8.—Surgeon L. B. Baldwin detached from the Key West naval station and ordered to hospital, New York, for treatment; Past Assistant Surgeon R. G. Brodrick granted sick leave for six months; Assistant Surgeon R. K. McClanahan detached from the naval hospital, Philadelphia, Pa., and ordered to the Key West naval station. July 10.—Past Assistant Surgeon L. L. Young sick leave extended three months. July 13.—Surgeon J. M Steele detached from duty in connection with recruiting rendezvous at Baltimore, Md., and ordered home to wait orders.

**The Late Dr. William H. Neilson.**—At a special meeting of the New Rochelle Medical Society, held July 7, 1899, the following resolutions were adopted:

"*Resolved*, That the members of the New Rochelle Medical Society desire hereby to express their deep regret at the sudden death of their late associate, Dr. William H. Neilson, and the great loss the profession and the community have suffered by the untimely removal of one of its most accomplished members.

"The society further desires to express the deepest sympathy for his family in their bereavement.

"*Resolved*, That as a further mark of respect for the late Dr. William H. Neilson, the above resolutions be spread upon the minutes of the society, a copy be sent to the family, and published in the MEDICAL RECORD and the New Rochelle papers.

"R. CONDIT EDDY, M.D., T. PASSMORE BERENS, M.D., C. NELSON RAYMOND, M.D., *Committee*."

**Obituary Notes.**—DR. J. WILLIAM NIEDECKER, of Brooklyn, died of apoplexy on an elevated road station July 17th. He was born in Cleveland, Ohio, and was thirty-eight years old. He was a graduate of Columbus College and of the Long Island Medical College. He began practice in Brooklyn about nine years ago. He leaves a widow and four sons.—DR. GEORGE W. BABCOCK, of Chelsea, Mass., died July 14th, at the age of eighty-four years. He was one of the founders of the Massachusetts Society of Medical Examiners.—DR. RUSSELL STURGIS, of Boston, died July 17th. He was a graduate of the Harvard University Medical School in the class of 1881.—DR. EDWARD S. GARNER, of St. Joseph, Mo., died July 6th, after a brief illness. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1883, and served on the house staff of the Presbyterian Hospital from 1883 to 1885. He was chief surgeon of the St. Joseph and Grand Island Railroad and was a member of the Missouri State board of health. He went to St. Joseph soon after finishing his studies here, and rapidly gained reputation and success as a surgeon.—DR. CHARLES J. SIGLINGER died of pulmonary tuberculosis at Philadelphia on July 12th, at the age of forty-two years. He was graduated from Jefferson Medical College in 1890.—DR. KATHARINE N. NORTHROP, resident physician at the Pennsylvania State Asylum for the Chronic Insane at Wernersville, died suddenly at Reading on July 15th. She was a graduate of the Woman's Medical College of Pennsylvania in 1889.—DR. JAMES GEARY, coroner's physician in the borough of the Bronx, died suddenly at his home Monday night, of heart disease. He was born in Morrisania in 1869, and was educated at St. John's College, Fordham. He received his medical degree from the Bellevue Hospital Medical College in 1892. In 1893 and 1895 he was house physician at St. Francis' Hospital. He leaves a widow.

## Obituary.

### JAMES ELLIOT GRAHAM, M.D.,

TORONTO, CANADA.

DR. J. E. GRAHAM, President of the Ontario Medical Association, and who was one of the best known members of the profession in Canada, died of diabetic coma July 7th, in his fifty-third year. He received his early education at Upper Canada College and graduated in Medicine at Toronto University in 1869, being gold and star medallist of that year. The following year he was resident physician at Brooklyn City Hospital, and left there on his appointment as surgeon without rank in the Prussian army, a position which he held through the Franco-Prussian war. After pursuing a post-graduate course in Vienna and London, where he obtained the diploma of L.R.C.P., he returned to Canada and commenced practice in Toronto in 1872. During the early years of his professional career he became identified with the medical faculty which has since been federated with Toronto University. In 1887, he was appointed professor of clinical medicine and medical pathology, and lecturer on dermatology. In 1892, he was appointed professor of medicine, which position he held at the time of his death.

Dr. Graham was president of the Canadian Medical Association in 1887, of the American Dermatological Association in 1889, and was one of the original members of the Association of American Physicians. He was largely instrumental in the organization of the Ontario Medical Association, and has always been numbered among the most active of the members of that society. His unanimous election to the position of president of that organization at its last meeting was a just and worthy tribute to one whose zeal for the welfare of the profession was at all times untiring. In matters pertaining to medical education he always took a deep interest and exercised great influence. His aim was ever to raise the standard. He took special interest in the practical aspects of medical education. He was himself an admirable clinical teacher, and did a great deal toward placing clinical instruction in the important position it now occupies in Canadian medical institutions. His position as a member of the senate of Toronto University gave him excellent facilities for fostering and developing the best interests of everything relating to medical education.

Dr. Graham was the first physician in Ontario who gave up general practice and devoted himself entirely to internal medicine. He was also the first physician in Ontario who became purely a consulting physician. For several years before his death he was generally recognized as one of the most prominent physicians in Canada. He loved the practice of medicine. Year after year he pursued his labors with a quiet sustained enthusiasm that could spring only from a genuine scientific spirit. Death took him in the plenitude of his powers. It has taken from the Canadian profession one who was always alert to its truest and best interests, and from his friends one whose place in their hearts can never be filled.

# Reviews and Notices.

THE PRINCIPLES OF BACTERIOLOGY. By DR. FERDINAND HUEPPE. Translated by DR. E. O. JORDAN. Chicago: The Open Court Publishing Co.

THIS is a very instructive book on the details of bacteriology, comprising a critical and comprehensive exposition of the same, based on scientific conceptions. The standpoints of the botanist, the general biologist, and the chemist have been utilized for the completeness of the work. The book is interspersed with illustrations, thus adding to its value. The translation has been well accomplished, and the book will certainly be a welcome addition to the physician's library.

DIE LARYNGO- UND RHINOLOGISCHEN UNTERSUCHUNGS-METHODEN. Von DR. GUSTAV ABELES, Assistent des Kaiser Franz Josef (früher Mariahilfer) Ambulatoriums in Wien, praktischer Arzt. Mit 25 Abbildungen im Texte. Leipzig: C. G. Naumann. 1899.

IN this little book of one hundred and fifty pages, the various methods in use for making nose and throat examinations are fully and clearly discussed. The first few pages are devoted to a *résumé* of laryngo- and rhinological technique, and the rest of the work is divided into three sections. The first of these treats of the examination of the mouth and the external parts; the second deals with laryngoscopy proper, together with the various manipulations that are practised on the larynx; while the third is devoted to the nares and nasopharynx. The book is written from the beginner's standpoint, and the many difficulties and mishaps inevitable to the tyro at this especially trying branch of surgical manipulation are described in turn, and their remedies suggested. The different models of instruments, lamps, etc., are well illustrated, and their comparative merits set forth. It would be unjust to the author not to mention the entertaining way in which he handles his subject and makes his little work most interesting reading, and it is to be hoped that it will meet with the recognition it deserves.

DIET IN ILLNESS AND CONVALESCENCE. By A. W. WINTHROP. New York: Harper & Brothers. 1899.

THIS little book is founded on "Diet for the Sick" published in 1885. Experience gained at Montauk Point, and suggestions from surgeons and nurses at the hospital camp, have been utilized. Valuable recipes, taken from the lips of accomplished cooks, have been printed, and thus we have before us one of the most valuable and instructive books on dietetics that have been published in years. At the same time we feel that illustrations (very poor ones) of patches in typhoid fever are certainly out of place, and can well be left out. Otherwise the book well fills its mission and can be utilized to advantage. The chapter on "Infant Feeding" is certainly very superficial, and cannot be used as a guide for the proper feeding of children.

CLINICAL LECTURES DELIVERED BEFORE THE STUDENTS OF THE IMPERIAL MOSCOW UNIVERSITY. By G. A. ZACHARIN, M.D., Late Professor (Emeritus) of Clinical Medicine and Director of the Therapeutical Faculty Clinic of the Imperial Moscow University; Honorary Member of the Imperial Academy of Sciences at St. Petersburg. Translated from the fifth Russian edition by ALEXANDER ROVINSKY, M.D., Member of the Massachusetts Medical Society. 487 pages. Boston: Damrell & Upham. 1899.

WE should feel extremely grateful that an opportunity is afforded us to read in English the ideas and teachings of the great Russian physician, he who did so much for his profession in his own country both scientifically and socially, who made it respected as it should be where, before his influence was felt, the doctor received scant courtesy. The lectures are most instructive, and we notice that unusual attention has been paid in them to the method of examining patients and to their treatment. His system of interrogation is an especially complete one, and will be of great interest to teachers of medicine. So, too, his careful hygienic instructions, the minute individual teaching which he gives each patient, the thorough exposition of his ideas concerning the mineral waters—how, when, at what temperature, and what kind should be given—all are particularly interesting The volume is so arranged that we have the history, physical signs, and laboratory evidences before we reach the diagnosis and treatment, thus arousing our interest and affording us as practical experience as could be given in a book. Among the many diseases presented to his clinic we notice those of the gastro-intestinal tract, pancreas, liver, and gall bladder, joints, kidneys, blood, and lungs. Twenty-three pages are devoted to balneotherapy, and as many more to cholera Among special articles are those on bloodletting, on calomel, on syphilis of the lungs and heart, and the treatment of fever.

A TEXT-BOOK OF ANATOMY BY AMERICAN AUTHORS. Edited by FREDERIC H. GERRISH, M.D., Professor of Anatomy, Bowdoin College. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1899.

IN this very handsome volume we have probably the best American contribution to didactic anatomy. The authors in their preface have stated their desire to present a work to take as much as possible the work of the living teacher, and they have omitted the enormous mass of detail which has accumulated in anatomical literature in the last decade. The book is divided into sections written by various authors, so that one or more sections form monographs by particular men on particular subjects, usually with very satisfactory results. The plates showing the origin and insertion of muscles are particularly good, and these, as well as those showing the vessels and ligaments, are up to the best standard. The plates of the bones are not quite up to the standard set by one or two other anatomical works. The book ought to make a very excellent one for the student to learn from, and will also serve as a refresher for the surgeon, Many of the figures are copies from several sources, notably Testut, and of this due acknowledgment is made.

LES VERRES ISOMÉTROPES. Par le DR. DE BOURGON. Paris: A. Maloine. 1899.

THIS monograph is a treatise on the physical and optical properties of spectacle lenses made of a new glass, of secret composition, devised and patented by Mantois, who, for some reason unexplained, has named it isometropic. A year ago these lenses were put on the market by la Maison Fischer, Paris, and they have been favorably reported on by several oculists and exploited in the lay press. The advantages of the new glass over the crown glass commonly used in spectacle lenses are, first, that it is more homogeneous, limpid, and transparent; and, second, that it is harder and of higher refractive index, so that for a lens of given focus the curvature is less and there is consequently less spherical aberration. On the other hand, the disadvantages of the new glass are its great dispersion and its excessive chromatic aberration, which render strong lenses of this composition useless. Pebble lenses, while hard and beautifully transparent, must be cut in a certain relation to the axis of the crystal in order to be satisfactory. The most singular property of the new glass is its impenetrability to the Roentgen rays, and while lenses of pebble or of crown glass, even though tinted, come out pale in a skiagraph, the isometropic lens comes out quite black. By thus cutting off the Roentgen and ultra-violet rays, the author states that the wearing of plane isometropic glasses alone has sufficed to relieve retinal asthenopia in several patients.

The treatise is very complete, and the author seems to have considered every aspect of his subject.

CHIRURGIE DE L'ESTOMAC. Par F. TERRIER, Professeur à la Faculté de Médecine, etc.; et HARTMANN, Professeur agrégé à la Faculté, etc. Paris: G. Steinheil, Editeur. 1899.

THIS volume is a complete work on the subject of its title. There are more than three hundred pages very well printed, and there are also scores of excellent engravings, many of them semi-diagrammatic and exceedingly helpful in elucidating the text. The first two chapters give us very complete descriptions of methods of examination of the stomach, and of the proper way of performing lavage. The operative surgery of the organ is then taken up, beginning with gastrotomy and going on through every operative procedure which has been attempted. The descriptions are concise and clear, and the bibliographical references unusually complete. The recent successes in removing the whole stomach are mentioned, and a very full description of the first case is

given. For the surgeon who wishes to know the present status of the surgery of the stomach, this is undoubtedly the book—if he can read French.

ELECTRO-HÆMOSTASIS IN OPERATIVE SURGERY. By ALEXANDER J. C. SKENE, M.D., LL.D., Professor of Gynæcology in the Long Island College Hospital, etc. New York: D. Appleton & Co. 1899.

THIS is, as it were, a supplement to the author's larger work on women's diseases. Advances in methods, instruments, and technique have been given greater elaboration. The work of one hundred and seventy-three pages is freely illustrated, and much explanatory description is rendered unnecessary by the drawings. The author advances some original and radical views upon the subject of electro-hæmostasis, which are of decided interest.

THE SURGERY OF THE HEAD AND NECK. By LEVI C. LANE, A.M., M.D., Professor of Surgery in Cooper Medical College, San Francisco. Second edition. Philadelphia: P. Blakiston, Son & Co. 1898.

THE author of this volume has attempted to make his work a complete treatise on the surgery of the head and neck. He has been successful in one way, and that is from the point of completeness, for on reading the pages it is next to impossible to think of any condition belonging under this title which has not been commented upon. The question of utility, however, is quite another matter, and the usefulness of a work of this kind is, we think, doubtful. The average reader or investigator wants rather monographs upon individual subjects by men who have been devoting special attention to those subjects, and he does not care to run through the numerous pages of a treatise of this sort only to find some more or less general information upon the matter in which he is interested. This book shows extensive knowledge and experience upon the part of the writer, who is also a man of erudition, and parts of it make interesting reading for the surgeon. There are very few illustrations for a book of its size, and the bookmaker's work leaves much to be desired.

RAILWAY SURGERY. A HANDBOOK ON THE MANAGEMENT OF INJURIES. By CLINTON B. HERRICK, M.D., Lecturer in Clinical Surgery, Albany Medical College, Surgeon to the D. & H. and the Fitchburg Railways, etc. Profusely illustrated. New York: William Wood & Co. 1899.

WE have in this volume a handbook upon a subject of growing interest and importance, on account of the increasingly prominent part taken by railways in modern life. The author has given us a volume of nearly three hundred pages, in which he discusses systematically the various forms of traumatism which occur among railway workers and passengers. There is a useful chapter upon sterilization and emergency work, and a description of a car hospital, which shows how far some railroads have advanced in this direction. The chapters upon the very severe crushes are naturally the most interesting in a work of this kind, since these are the most characteristic injuries. Conservatism, wherever possible, is strongly advised, and excellent advice for the performance of amputations, when necessary, is given. The illustrations are numerous, and of very high class. There is also a chapter upon traumatic neurasthenia.

CYCLIC LAW. By THOMAS E. REED, M.D., Middletown, Ohio. 1898.

SINCE a supra-eminent German professor, who administered remedies for chronic diseases according to the ebb and flow of the tides, taught the author that births occurred at the flow and deaths at the ebb, he has for many years made the matter a subject of investigation, and now publishes the results of his observations for the edification of the profession. In one hundred and sixty-seven 16mo pages are discussed many problems, including the laws governing sex and tide cyclic influence in the obstetrical field. Many "original observations" are made, which the author believes if applied in practice will be found "vastly valuable" in prolonging and saving human life. The reader will undoubtedly be edified by this book, and at its completion will agree with the writer "that which we know is little, that which we are ignorant of is IMMENSE."

## A CASE OF COMPLETE LARYNGECTOMY FOR EPITHELIOMA—RECOVERY.[1]

By F. C. ARD, M.D.,

ASSISTANT SURGEON NEW YORK EYE AND EAR INFIRMARY; ATTENDING SURGEON EYE AND EAR DEPARTMENT, MUHLENBERG HOSPITAL, PLAINFIELD, N. J.

THE patient I present for your examination this evening has recovered from two radical operations on the larynx within the past five months. The first, a partial laryngectomy, was done on November 28, 1898, and owing to a recurrence of the growth within a few weeks a complete laryngectomy was done on February 19, 1899, from which she has made an excellent recovery.

Mrs. H——, married, aged forty-one years, was referred to me in June, 1898, by Dr. W. H. Murray. At that time the only symptom of which she complained was hoarseness. The family history, so far as it could be obtained, was good; her mother is living at the age of eighty years. There was neither history nor evidence of syphilis. She has always enjoyed good health with the exception of annual attacks of tonsillitis. The hoarseness dates from one of these attacks in October, 1897, and had been continuous up to the time of her first visit to my office. On laryngoscopic examination I discovered an irregularly shaped mass of reddish color situated just above the anterior commissure of the vocal cords and projecting into the cavity of the larynx. There was no infiltration of the surrounding tissues. The vocal cords were normal in appearance, with movements unimpaired, and the growth was not ulcerated. There was absence of pain, dysphagia, and dyspnœa, and there was no evidence of glandular infection. The growth had every appearance of a papilloma, and I so considered it at that time. Within a few weeks a troublesome cough developed with considerable inspiratory dyspnœa, and as alcohol sprays had been tried faithfully, and the patient had taken liberal doses of potassium iodide without results, I removed the growth in the latter part of July, using the McKenzie forceps. Shortly after this I left town on my vacation, and did not again see the patient until early in September. She then stated that for a period of two or three weeks after the removal of the growth she had been very comfortable; she had had no dyspnœa, her voice was much improved, and she had had very little cough, but the symptoms had gradually returned until her condition was, as she expressed it, "as bad as ever." Examination showed a recurrence of the growth at the original site, and it was almost as large as before.

The tissue removed in July, having been preserved, was handed to Dr. B. Van D. Hedges, pathologist to Muhlenberg Hospital, for microscopical examination. He reported the growth to be an epithelioma, and that his diagnosis had been confirmed by Dr. Tuttle of the Presbyterian Hospital laboratory. Specimens were also sent to the laboratory of the College of Physicians and Surgeons, and the following report was received:

"Typical epithelioma; the whole specimen is overrun by branching and anastomosing columns of epithelial cells which do not repeat the normal structure of the corium; hypertrophy of papillæ is insignificant, and the growth has no resemblance to any of the papillomata. There are many epithelial pearls and cell nests, and masses of prickle cells. The cells in general are very large and atypical, many of the nuclei

[1] Read before the section on laryngology and rhinology, New York Academy of Medicine, March 22, 1899.

showing karyokinetic division figures, and the tumor looks as though it could grow rapidly. There is a moderate degree of inflammation, but in the specimen no ulceration. The whole thing is purely an epithelial invasion."

Dr. Emil Mayer saw the case with me at this time and stated his belief that the growth was an epithelioma. The diagnosis of malignancy being established and the case being a favorable one for operative procedure owing to the localized character of the growth, I referred the patient to Dr. George Emerson Brewer for an opinion. He advised a partial laryngectomy, and on November 24th, at the hospital of the Private Hospital Association, did a partial laryngectomy, a preliminary tracheotomy having been done several days before. An incision, extending from the hyoid bone to the first ring of the trachea, was made into the larynx. The growth with the vocal cords and the anterior third of each thyroid cartilage was removed. The patient left the hospital in about two weeks.

Shortly after she returned to Plainfield I made an examination of the larynx, and found in the same situation what closely resembled granulation tissue. As this has been mentioned in the history of cases reported particularly by Semon, it gave me no concern, but its subsequent growth, together with the rapid development of former symptoms, soon demonstrated that we had to deal with a recurrence. The patient's condition was such on February 18th that I removed her to Muhlenberg Hospital, where a tracheotomy could be quickly done if necessary, and on February 19th I asked Dr. Brewer to see her again with Dr. Murray and myself. The result of the conference was to offer the patient the only chance for recovery by advising a complete extirpation of the larynx. The patient and her family accepted the advice, and she was immediately prepared for operation.

Under chloroform anæsthesia, Dr. Brewer made an incision in the median line, from the body of the hyoid bone to the suprasternal notch. The trachea was opened below the isthmus of the thyroid, the upper segment of the tube was plugged with sponge, and the cannula was introduced. From the upper extremity of the incision were made two additional incisions extending obliquely upward toward the angles of the jaw. The two superior thyroid arteries were found and ligated, and although no enlarged lymphatic glands were found, the areolar tissue surrounding the vessels was removed. The larynx and upper part of the trachea were then cleaned and separated from their muscular attachments; the trachea was divided and the posterior surface of the cricoid carefully dissected from the œsophagus. The pharynx was not opened until the larynx had been entirely freed from its attachments to all surrounding structures, when the two were separated. The resulting pharyngeal wound was completely united with catgut, the trachea sutured to the skin, and the incision partly closed and packed.

The patient's condition after coming from under the anæsthetic was excellent, due, I believe, to a rapid and almost bloodless operation and the skilful manner in which Dr. Murray administered the chloroform, alternating it with oxygen so that she received a very small quantity of the former. The patient was placed in bed, and gauze compresses of warm boracic solution, changed every five minutes, were kept over the tube. The temperature for the first few days was above normal, ranging from 100° to 102° F. The tube in the tracheotomy wound was retained for forty-eight hours and then removed, owing to the irritation it was causing, and the patient was allowed to breathe through the upper end of the trachea, which was sutured to the skin margin of the wound. That same night I was called hurriedly to the hospital to find the upper end of the trachea almost filled with a gummy material, and the patient breathing with considerable difficulty. The emergency had been met by the nurse inserting the trachea forceps in the tracheotomy wound, and administering oxygen until my arrival. With some difficulty the tube was inserted in the upper opening, and the patient again breathed comfortably. For the first four days the patient was nourished by rectal enemas, and on the fifth day teaspoonful doses of milk and Vichy were given by the mouth. This was gradually increased until she was able to take four ounces at a time. Slight leakage through the pharyngeal wound was noticeable for a few days, but was not sufficient to cause us to discontinue nourishment by the mouth. The cough has been troublesome at times, and prompt action has been necessary on occasions when the tube became plugged with thick, tenacious mucus. For two weeks after the operation the patient was not left alone for a moment, and I believe this constant watchfulness and care have in no small degree contributed to her recovery. At the present time the patient is able to converse with her friends in a whisper, and is easily understood.

Plainfield, N. J.

## INTESTINAL OBSTRUCTION IN A NEWBORN CHILD.

By G. HERBERT CARTER, M.D.,
Huntington, N. Y.

The following case has been instructive to me, and is, I think, quite unusual.

Mrs. C——, aged twenty-two years, was delivered of her first child March 10th, at 8 P.M. The labor was normal. The child appeared normal at birth. I called on March 11th, at 10 A.M., and found that the child had had no movement of any sort. Repeated enemas (soapsuds) were given, with no result. That evening the child began to vomit; the abdomen began to swell, and the child seemed to be in some pain. He was put on small, repeated doses of castor oil, and later of calomel, but vomited everything put into the stomach. For three hours enemas of warm water, glycerin, and castor oil were given, with absolutely no effect except to bring away a little bright blood.

No tumor could be felt anywhere in the abdomen, but the swelling (tympanites) steadily increased.

This state of affairs continued during the 12th, and on the evening of that day vomiting became distinctly fecal. In consultation with Dr. Lindsay it was decided not to operate, the surrounding conditions not being encouraging, and the child apparently being near its end.

Fecal vomiting continued during the 13th and 14th, day and night. Tympanites increased and became enormous. The child rapidly lost flesh and seemed completely exhausted. On the 15th all attempts at feeding were stopped, and vomiting then stopped. Enemas then had no result and seemed to give great pain.

At 5 A.M. of the 16th, *i.e.*, when the child was five and one-half days old, and had had absolutely no movement, not even the passage of flatus, since birth—he began to cry hard and strain, and soon had a large, black, tarry, very offensive movement. At intervals of half an hour his bowels kept moving all day, so that during the day he passed an enormous amount of fæces. In twenty-four hours he showed the first signs of hunger and took the breast for the first time, and has gained in weight ever since; the tympanites rapidly subsiding.

The child gave every symptom of a complete congenital intestinal obstruction, persisting for five and one-half days, and yet, contrary to the prognostications of his physicians, he entirely recovered.

I confess my ideas as to when we should operate on a case of intestinal obstruction have become confused.

## THE PRACTITIONERS' SOCIETY.

*One Hundred and Forty-Seventh Regular Meeting, Held on Friday, April 7, 1899.*

W. GILMAN THOMPSON, M.D., PRESIDENT, IN THE CHAIR.

**A Case of Secondary Carcinomatous Infiltration Treated with Guaiaquin.**—This case was presented by DR. BEVERLEY ROBINSON. The patient was a woman, forty-six years old, a seamstress by occupation, who was operated on at the Newport Hospital for carcinoma of the breast in August, 1896. About a year later a second operation was found necessary. Subsequent to this operation, the patient's arm on the affected side became swollen and painful, and she came to Dr. Robinson for relief. After employing several remedies ineffectually, the speaker said, he was induced to try guaiaquin (guaiacol bisulphonate of quinine), which was supposed to possess the characteristic properties of both guaiacol and quinine. The patient began taking three grains of this drug three times daily in October, 1898, and continued it steadily for four months; during this period she improved markedly; both the swelling and pain disappeared, the patient slept better, and she felt better generally. In February, 1899, when the administration of the guaiaquin was interrupted for three weeks, the patient had a relapse; the arm again became swollen, and the supraclavicular space was evidently more infiltrated, although her pain did not return. During the past month the patient had resumed the use of the drug, and the swelling of the arm had again disappeared, at least to a large extent. During the past few days she had complained of an aching pain in the arm, which a tight glove seemed partially to relieve. Massage had also been useful at times. Several examinations of the patient's blood had been made by Dr. Frederic E. Sondern with negative results. Dr. Robinson said he was induced to try guaiaquin in this case as an experiment, and he simply reported the result in the hope of inducing other members to give it a trial under similar circumstances, because these cases were often very troublesome and painful, and any remedy which would mitigate the symptoms should certainly be welcomed. Furthermore, recent investigations seemed to demonstrate that carcinoma was a parasitic disease, and from that standpoint medical intervention, with the use of drugs or serotherapy, again assumed practical value. The speaker said he had tried guaiaquin in several cases of malaria with rather uncertain results.

**Three Cases of Drop-Finger.**—DR. ROBERT ABBE showed a photograph of a case of what he had called "drop finger" five years ago, when he reported two cases (*New York Medical Journal*, January 13, 1894). He drew particular attention to the disproportion between the cause of the accident and the accident itself. The extensor tendon was torn from its attachment to the back of the near end of the last phalanx of the finger by some apparently insignificant force, well illustrated in the three cases reported. This patient, a lady, was pressing her fingers down her thigh, holding a towel, after her bath, and suddenly noticed that the right ring finger had dropped at the end joint and was useless. There had been no pain accompanying it, and there was no hemorrhage about the joint. In the second case, an architect was brushing the crumbs of rubber from his drawing paper, and the end joint of his middle finger dropped useless, also with little more than a sensation, but not pain. In the third case, a lady was taking off her stocking after a walk, and on pressing it down the outer side of the calf of her leg, which was damp, suddenly felt the end joint of her middle finger drop helpless.

Dr. Abbe's explanation of the accident was that the tendon was very thin as it expanded to be attached to the broad base of the bone, and that while the force exerted ordinarily to extend the end would be very great before the tendon would snap, if it was exercised in the axis of the finger it would take but little force to tear it if the finger was pressed sidewise during the extensor strain. The principle was illustrated by a narrow strip of paper which would bear great strain lengthwise, but would tear if a trifling force was applied at the edge.

FIG. 1.

All three cases reported he had operated on successfully under cocaine applied along a dorsal incision. The capsule of the joint was found to have fallen into the joint, while the lacerated tendon was but slightly displaced. Two finest silk stitches served to keep the parts apposed, and excellent repair followed.

**Pancreatic Cysts: Three Cases.**—Dr. Abbe presented drawings and histories of these cases, remarking that they illustrated well the relation of the stomach and colon to the cyst. It had been shown by Körte ("Surgical Diseases of the Pancreas," Stuttgart, 1898) that these relations were not at all constant. In Fig. 2, shown by Dr. Abbe, the stomach was below the cyst, in Fig. 3 above it, and in Fig. 4 upon it. The speaker said that a knowledge of this wide variation was valuable, and aided much in making the diagnosis in two of his cases. It occurred rarely that the colon lay upon or even above the major part of these cysts. In the three cases narrated, a prompt and radical cure was effected by drainage.

CASE I.—The patient was a woman who was referred to Dr. Abbe in July, 1898, by Dr. Bogardus. She had previously been operated on by a surgeon in a neigh-

boring city, who, upon opening the abdomen, found a large tumor, which he regarded as a cancer of the

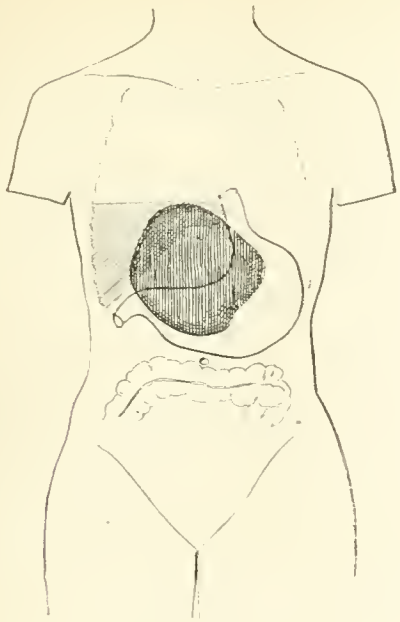

Fig. 2.—Case I.

stomach and pronounced it inoperable. Dr. Abbe performed a second laparotomy, and found a large pancreatic cyst lying behind and above the stomach; it was filled with a clear fluid and its walls were everywhere lined by shreddy tissue, semi-necrotic in character, and mixed with much calcareous matter in cakes and rough pieces. The cyst was cleaned and drained, and the patient made an excellent recovery.

Case II.—The patient was a woman, who gave a long-standing history of stomach trouble. More re-

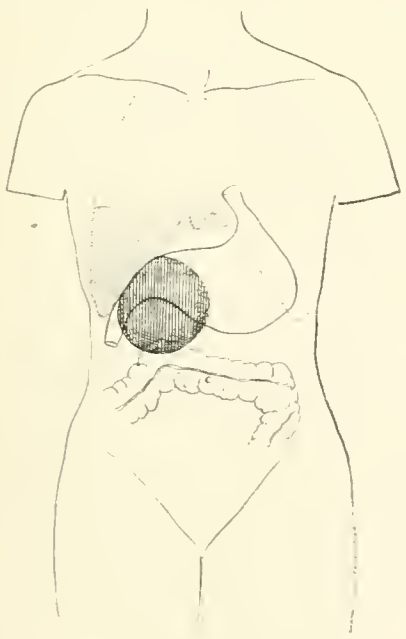

Fig. 3.—Case II.

cently she complained of acute pain, intermittent in character, and the presence of an epigastric tumor, which occasionally grew smaller and then enlarged again. At times she vomited a dark, clear fluid and had bloody dejections, followed by clay stools for a day or two. Examination showed an oval tumor, like a greatly distended gall-bladder, extending from the tenth cartilage to the navel. The pylorus and stomach were raised on the upper part of the tumor, along the edge of the ribs. The patient was operated on by Dr. Abbe on September 6, 1898. A pancreatic cyst, filled with coffee-colored fluid, was found; it also contained a number of small-sized calculi. The cyst drained for

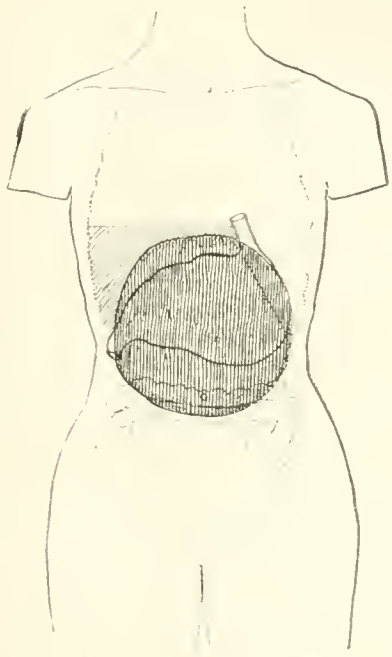

Fig. 4.—Case III. Front View.

some time, the sinus finally closing in December, 1898. The patient made a good recovery.

Case III.—The patient was a woman, thirty-two years old, who for eight months had suffered from pain in the back, with vomiting. No jaundice. Soon afterward an abdominal tumor was noticed. The vomiting gradually passed off, and there were no other digestive symptoms. The tumor gradually increased in size, however, and gave rise to much discomfort and some difficulty in breathing. It was oblong and

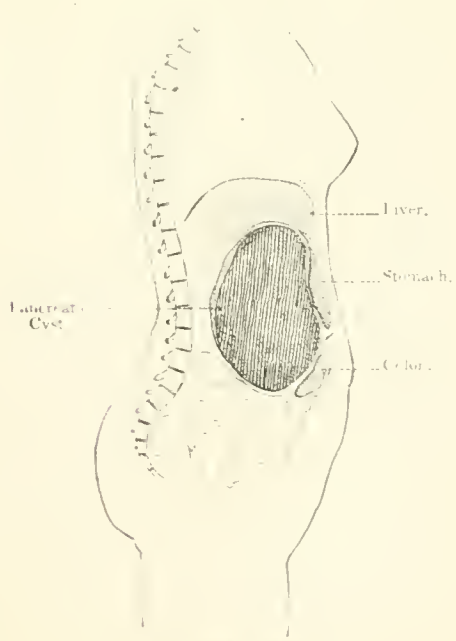

Fig. 5.—Case III. Side View.

spherical, extending into both lumbar spaces. The patient was operated on by Dr. Abbe on April 7, 1899. He found, as he had expected, a pancreatic cyst, which contained about half a gallon of a clear, coffee-colored

fluid, the specific gravity of which was 1.016; it was markedly alkaline and contained about twenty-five per cent of albumin, also some cholesterin crystals; no sugar. It was capable of digesting both starch and albumin. The cyst was incised and drained through the gastrocolic omentum. The patient made an uneventful recovery.

Dr. G. L. Peabody thought it was rather unusual not to have jaundice in these cases, as the cyst, if of large size, generally pressed on the common duct. Several years ago, the speaker said, he saw a case of pancreatic cyst which had been mistaken by several physicians for cancer of the stomach. The true diagnosis was not made before the autopsy.

Dr. Abbe, in reply to a question, said that drainage seemed to effect a permanent cure.

Dr. E. G. Janeway said the presence or absence of jaundice depended somewhat upon the location of the cyst. He had seen two cases, in both of which jaundice occurred. If the head of the pancreas was not involved, there might be no jaundice. The speaker referred to two cases of pancreatic cyst coming under his observation in which no tumor could be made out, and the condition was not recognized during life. Regarding the etiology of some of the deep abdominal cysts, some writers have regarded them as originating from the remnants of the Wolffian bodies. Dr. Janeway also drew attention to the possibility of some of the supposed pancreatic cysts being intraperitoneal.

In reply to a question by Dr. Robinson, Dr. Abbe said that in the cases which he had observed there was nothing in the stools to aid in the diagnosis. He regarded them as retention cysts.

**Combined Sclerosis of the Cord, and Spinal-Cord Changes in Pernicious Anæmia.**—Dr. Charles L. Dana read a paper on this subject, and in connection therewith showed a number of microscopic sections (see p. 897, vol. 55).

In reply to a question, Dr. Dana said that in a large proportion of cases of pernicious anæmia—over one-half—there were some slight changes in the cord. In about twenty per cent. of cases of combined sclerosis we got pernicious anæmia.

Dr. Janeway said that some of the nervous symptoms sometimes observed in cases of pernicious anæmia might be due to the toxic doses of arsenic which were often administered in this disease. He had seen cases of pernicious anæmia of a very severe type without any accompanying dementia or nervous phenomena. Four such cases had very recently been under his observation. Of course, in some cases the nervous symptoms were quite marked; in others there was an absolute failure of nutrition, the functions of the stomach being almost entirely in abeyance.

**Shock in Modern Surgery.**—Dr. George F. Shrady read a paper with this title (see p. 112).

Dr. Clement Cleveland said that in his special field of surgery he saw very little of shock, and he no longer feared it as much as formerly as a factor in abdominal or intrapelvic work. It had been almost entirely eliminated. He ascribed this marked change to the fact that in doing his operations he almost invariably placed his patients in the Trendelenburg position the very position which Dr. Shrady, in his paper, said he regarded as a factor in the production of shock. In the Trendelenburg position, the intestines, with their sensitive serous covering—the most sensitive membrane in the body—were carried out of the way of the field of operation and were in consequence very little disturbed or handled. Dr. Cleveland mentioned, as a second factor in the prevention of shock, the use of decinormal salt solution, which had now become so general. It was rapidly taken up by the peritoneum, which was really one immense lymphatic sac, and thus reached the general circulation, and was as potent in this way as a restorative agent as if it had been injected directly into a vein.

Dr. Dana said that, in operations on the brain, one of the most important factors in the prevention of shock was to get through the skull quickly and without hammering. This had been the uniform experience of all neurologists who had watched cranial surgery. The operation of craniectomy, for example, as formerly done with the hammer and chisel, was attended with a mortality of over ninety per cent.; now, by means of the electric saw, the operation could be done in fifteen minutes, with a mortality of not over five or six per cent. This applied particularly to children, on whom the operation should be done even more quickly than on adults.

Dr. V. P. Gibney said he agreed with what had been said and fully indorsed Dr. Shrady's plea for less prolonged operations and the use of a less quantity of ether or other anæsthetic. Many surgeons were in the habit of unnecessarily delaying an operation after the patient had been anæsthetized; instead of permitting the patient to be soaked with the anæsthetic while the surgeon was preparing himself, the latter ought to be ready before the anæsthetic was given, unless his time was too valuable. Dr. Gibney also suggested that shock might in some cases be averted if the anæsthetic was given, so far as was possible, by men specially trained for that work. In London a society of anæsthetists had been formed, who were making advances along this line quite rapidly. He said he was glad to hear Dr. Cleveland's remarks about the Trendelenburg position. In his own operative work he was careful to see that the foot of the operating-table was raised quite high, and he felt convinced that this procedure was of value. In operations on the long bones, he thought the chisel was superior to the saw, quicker and more thorough work being done. This, of course, did not apply to operations on the skull.

Dr. Abbe said that, while he was interested in the revival of this question, he was not inclined to believe that the length of time of an operation was of such grave import as Dr. Shrady ascribed to it. Of course it had some influence on the production of shock, but frequently, in order to do the operation thoroughly, it was necessary to prolong the anæsthetization for an hour or even longer, and these patients did not die of shock. In most instances when shock occurred it could be traced to extensive injury of the cranium, or, in abdominal surgery, to strangulation or prolonged cleansing or manipulation, or to excessive hemorrhage. The speaker said he had come to regard hemorrhage as a more important factor than time. In the prevention of shock he laid great stress upon sustaining the bodily temperature during the operation. The sudden exposure of the surface of the body to the air produced considerable shock, even when one was well and conscious, and the surgeon was apt to overlook this when dealing with the unconscious patient. In order to guard against it, only that part of the body which was to be operated on should be exposed; and if much surface was exposed, hot cloths should be kept on the epigastrium. In doing his operations, he always assigned one nurse to do this work. In children, who are especially prone to shock, he had been able, in three cases, to remove enormous kidney tumors through large abdominal incisions and avert shock simply by keeping the patients enveloped in cotton and, in addition, covered with warm blankets and lying on a warm table. In cases in which an excessive quantity of blood was lost, saline infusions were always desirable, and their value was beyond question.

Dr. Francis P. Kinnicutt said it had recently been stated by apparently careful English observers that a large proportion of the deaths following operation

were the result neither of shock nor of the various other factors which had been mentioned, but were due to ether pneumonia. He had personally observed a certain number of such cases. The professional anæsthetists had become fully alive to this danger, and recently had tried to combat it by rendering as aseptic as possible the mouth and nasal passages of the patient before administering an anæsthetic, thus hoping to diminish the number of cases of ether pneumonia.

Dr. Janeway said he had seen cases of ether pneumonia, but in such instances death did not occur within twenty-four or forty-eight hours, as it did usually from shock. The possible occurrence of such a pneumonia is one of the reasons advanced by English and German surgeons for preferring chloroform to ether.

Dr. Beverley Robinson said that surgeons were sometimes not quite careful enough to allay the apprehension of the patient prior to the operation.

Dr. Shrady, in closing, said that he was much gratified that his paper had elicited so much profitable discussion. In reference to employing the Trendelenburg position, he did not intend to imply that it should be ignored entirely; in fact, many operations could scarcely be done without it. In his paper he referred more particularly to those instances in which the extreme position was resorted to, especially in prolonged operations on fat persons with heavy abdominal organs. Under such circumstances he had seen some alarming symptoms which disappeared when the patients were put in the horizontal position. He said he had seen cases of ether pneumonia not infrequently, especially since his attention had been called to it by the English writers. In such cases the urgent symptoms usually appeared within twenty-four hours, and death occurred in two or three days.

**A New Sphygmometer.**—Dr. Walter B. James demonstrated the workings of a new sphygmometer devised in England by Messrs. Hill and Barnard. By means of this apparatus the pressure of the blood in the blood-vessels could be demonstrated and recorded.

## AMERICAN NEUROLOGICAL ASSOCIATION.

*Twenty-Fifth Annual Meeting, Held at Atlantic City, N. J., June 14 and 15, 1899.*

Dr. James Hendrie Lloyd, of Philadelphia, President, in the Chair.

*First Day—Wednesday, June 14th.*

The annual address was delivered by the president.

**The Nervous Equivalents of Fever.**—This paper was read by Dr. Henry S. Upson, of Cleveland. He said that although it was usually easy to distinguish organic from functional disease in the nervous system, the problem became a difficult one when it was necessary to differentiate functional nervous troubles pure and simple from disease of other organs with nervous symptoms. After citing several illustrative cases, the following conclusions seemed to the speaker to be warranted: (1) Fever was a nervous reaction, usually to toxins; (2) fever was often accompanied by other nervous reactions; (3) other nerve reactions to toxins, whose form was largely determined by the predisposition of the patient, might occur without fever, and might replace it. These reactions might simulate very closely hysteria, mania, and melancholia.

**Isolated Finger Paralysis.**—Dr. William Browning, of Brooklyn, presented photographs, post-mortem findings, and histological report of a case of this character. The patient was a vigorous man over seventy years old, in whom at an interval of one and one-half years the extensors of the right middle and ring fingers became suddenly paralyzed. Each attack occurred at the instant of muscular effort. The condition remained unchanged until death some years later. The autopsy showed destructive lesion of the corresponding muscles and tendons.

Dr. F. X. Dercum, of Philadelphia, thought the subject was unique, inasmuch as nothing was known about the senile changes that took place in the tendons. In the case reported the break in the tendon was produced by muscular effort, and the other changes were the ultimate result.

Dr. Browning was inclined to attribute these changes to the obliterating endarteritis which was present.

**Amaurotic Family Idiocy.**—Dr. Hugh T. Patrick, of Chicago, exhibited water-colors of fundus appearances in two cases of amaurotic family idiocy, and briefly narrated the histories. One of the children was of Christian parentage.

Dr. Joseph Collins, of New York, asked for further information regarding the clinical history of this case, as all of the cases thus far reported had occurred in Hebrew children.

Dr. W. M. Leszynsky, of New York, had seen four cases of this disease. From the ophthalmoscopic picture alone he would be unwilling to make the diagnosis, for the condition of the fundus in this affection bore a striking resemblance to that seen in embolism of the central artery of the retina.

Dr. Patrick said that the diagnosis seemed reasonably sure. His own case was that of a child aged sixteen months, who had developed perfectly up to the age of nine months. Then it began to fail. It did not speak or attempt to speak now, and had the general nervous condition that was so characteristic of these cases. The other child had not been under his observation. He had merely presented the picture of its ocular fundus.

**The Unity of the Acute Psychoses.**—This was the title of a paper by Dr. Philip Coombs Knapp, of Boston. He stated that there were several forms of melancholia, differing so much in type as to suggest different diseases. Melancholy seemed rather a symptom than a disease by itself. The existence of mania, acute paranoia, and many other acute mental diseases was questioned, most writers disagreeing in their classification. A symptomatic classification of mental diseases was often fallacious and unsatisfactory. Alcohol might cause a number of different types of psychosis. The acute psychoses were often of toxic origin; they might attack healthy persons, they might cause death by exhaustion, recover completely, or end in dementia or chronic delusions. They were regarded as probably one affection, under the general heading of Meynert's amentia.

Dr. Charles K. Mills, of Philadelphia, said it seemed to him that much in the paper meant a distinct step backward in our method of looking at these diseases. If the author pretended to place together diseases so distinct clinically, pathologically, and etiologically as paranoia, melancholia, and mania, he had no ground whatever upon which to stand. One point in the paper, that of the unity of certain acute psychoses, in a general way might be admitted, but it was by no means a new thought, for it had long been discussed as to whether acute mania and acute melancholia, and perhaps acute delirium, were not diseases of the same origin, whether that be toxæmia or not. Because some cases of melancholia passed to dementia, and because all cases of paranoia did so, was no reason why they should be regarded as the same disease, either pathologically or clinically.

Dr. F. X. Dercum, of Philadelphia, agreed with the views expressed by Dr. Mills. In his opinion

there was no resemblance between neurasthenia and melancholia because a patient who developed melancholia passed through a series of vague symptoms that resembled neurasthenia. Regarding the different forms of insanity, he thought that if Dr. Knapp's views were adopted it would be necessary to abandon all that had enabled us to sift out these disorders.

Dr. H. T. Patrick, of Chicago, said that there could be no objection to placing all the psychoses in one general class with similar symptoms. He agreed, however, with Dr. Mills that in adopting such a standard we should be making a step backward. The tendency was and should be toward a differentiation between these diseases if it would help in the treatment.

Dr. Henry S. Upson, of Cleveland, did not believe that acute melancholia and acute mania were the same. He believed that these diseases had a definite chemical basis that probably would be proved ultimately to be toxic, and probably back of that to be due to bacteria, but meanwhile the best thing would be to make the classification from the symptom complex.

Dr. Joseph Collins, of New York, saw no objection to considering all the forms of insanity as of a smilar nature. If all psychoses were looked upon as having a definite unity, the treatment would be hampered.

Dr. J. W. Putnam, of Buffalo, said that it was not possible to tell what type of mental change was going to result from a given etiological factor; as the result of fright there might be acute dementia, melancholia, or mania. He assumed that Dr. Knapp himself would make his prognosis depend largely upon the etiology.

Dr. Knapp, in closing the discussion, said that Dr. Mills and Dr. Dercum had misunderstood him in supposing that he would place paranoia, melancholia, etc., in the same group with acute diseases. He did not attempt and should not think of classifying the true typical paranoia, the true general paralysis of the insane, with the acute mental disturbances, such as acute mania, acute melancholia, and acute confusional insanity. In his paper he spoke of the similarity of the acute psychoses. He agreed with Dr. Upson that the cases could not be classified on an absolutely anatomical basis. The prognosis was judged by the severity of the attack, and by its whole clinical aspect, but the whole number of cases was regarded as one disease, though the prognosis depended upon different symptoms in the individual cases. One would not treat every case of typhoid fever in the same way, and it was not necessary to treat all cases of mental disease in the same way simply because they belonged to a given class.

**Tumor of the Medulla.**—Dr. F. X. Dercum read the report of a case of tumor of the medulla, presenting ataxia and astereognosis as the most prominent early symptoms.

**Tumor of the Pituitary Body.**—Dr. George L. Walton, of Boston, reported a case and exhibited the morbid growth. The patient was a physician, twenty-six years of age, who first came under Dr. Cheney's observation with unilateral hemianopsia (right) and asthenopia (left). Optic atrophy followed, with increasing loss of vision in both eyes. Later homonymous hemianopsia appeared, and still later achromatopsia in the otherwise normal half field of the right eye. Muscular weakness, apathy, intense headaches, and somnolence appeared and increased. A striking feature of the case was the fact that the patient had always had very large extremities and features, with large jaws and separation of the teeth. The hair was dry and crisp. The autopsy showed angiosarcoma of the hypophysis with disappearance of portions of the sella turcica. Certain remains of normal gland structure were found. He drew the following conclusions: (1) Congenital peculiarities in growth resembling those of acromegaly might point to defective structure of the gland later the seat of new growth; (2) the persistence of even a small amount of healthy gland tissue sufficed fairly to carry on its function; (3) the combination of general symptoms of new growth with loss of one or both temporal fields and optic atrophy practically established the diagnosis of tumor of the pituitary body, (4) hemiachromatopsia was not necessarily of central origin.

**Glio-Sarcoma of the Middle Fossa of the Skull.**—This case was reported by Dr. Morris J. Lewis, of Philadelphia. The patient was a girl, eleven years of age. Soon after extraction of the lower right molar tooth she had considerable pain, quickly followed by right-sided earache, and in three weeks by right facial palsy, soon becoming total. Four months later a trophic ulcer appeared on the cornea. Subsequently there was complete right facial palsy, the muscles presenting the reaction of degeneration. The tongue was protruded to the right; the sense of taste was destroyed on the right side of the tongue except at the tip and base, in which it was impaired, sensation being destroyed over the posterior two-thirds. The fundus of the right eye could not be seen on account of cloudiness of the media, but a commencing optic neuritis was detected, which rapidly increased to 3 D. The ear showed evidences of past suppurative changes. The second, third, fifth, sixth, seventh, eighth, and ninth nerves on the right side were all more or less implicated, but absolutely no symptom referable to implication of the trunk or extremities could be detected. Violent headache and retraction of the head, coming and going, appeared before death, which occurred forty days after admission to the hospital. Treatment was of no avail. The autopsy revealed a large glio-sarcoma filling the whole of the right middle fossa of the skull, with erosion of the sphenoid and temporal bones and protrusion of the mass into the pharynx. The right temporal lobe of the brain was completely hollowed out by pressure.

**Tumor of the Brain.**—Dr. James Hendrie Lloyd, of Philadelphia, presented a specimen of tumor of the brain. The growth sprang from the membranes on the left side of the pons and medulla. It had made pressure upon the left lobe of the cerebellum, which was much flattened by it. It was in position to involve the seventh and eighth nerves on the left side, and also to press upon both sixth nerves. It did not extend so far as the fifth nerve. The symptoms had been quite characteristic, and led, without difficulty, to a correct diagnosis during life. The patient had been under observation for one year and a half before death. The early symptoms had been vomiting, headache, vertigo, and diplopia. Very soon a conjoint paralysis of the left sixth and seventh nerves developed. Deafness on the left side supervened. Later the right sixth nerve also became involved. The general symptoms of brain tumor (with optic neuritis progressing to total blindness) increased in gravity. There was never hemiplegia or paralysis of any kind in the limbs. No anæsthesia occurred. There were no convulsions or any distinct cerebellar symptoms, such as ataxia or forced movements. Considering the large size of the tumor (about as large as a hen's egg), the absence of cerebellar symptoms or of pressure symptoms in the pons or medulla was noteworthy. It was difficult to see how the middle cerebellar peduncle escaped, and yet no forced movements to either side were observed. In another case observed by Dr. Lloyd, in which the tumor was in much the same location as this one, forced movements were the most marked symptom, and the seventh nerve entirely escaped. The difference was explained by the fact that the tumor was only half as large as the present one

and was embedded slightly farther in the middle cerebellar peduncle. The motor and sensory tracts in both pons and medulla escaped in the present case, although the growth was in nearly the same position as the one just described by Dr. Dercum, in which motor and sensory symptoms were marked. These differences strikingly illustrated the well-known fact that brain tumors in practically (but of course not identically) the same position could give rise to widely differing clinical pictures.

These four papers were discussed together.

Dr. F. W. Langdon, of Cincinnati, in referring to Dr. Dercum's case, said that the stereognostic sense is formed by fusing a great many sensations. The location of the lesion was significant in this case, as it involved the labyrinth, and it would have been of interest to test the functions of the internal ear in such a case.

Dr. Dercum replied that the ears were examined, but there was nothing found to suggest the involvement of the fibres coming from the labyrinth.

Dr. Walton added that his final conclusions were almost to be taken for granted, as the combination of general symptoms of new growth with loss of one or both temporal fields and optic atrophy practically established the diagnosis of tumor of the pituitary body.

**Asthenic Bulbar Paralysis.**—This was the title of a paper by Dr. Wharton Sinkler, of Philadelphia, who said that the attention of the medical profession was directed to this disease in 1892. Up to 1895 there had been twenty-two cases reported. Twelve additional cases had since been published. Three of these were in America. The speaker laid stress upon the fact that the essential feature of the disease was the rapid fatigue which was shown in the affected muscles when used, and the fact also that there was not complete paralysis of any muscles, but rather a tendency to give out upon use. The intensity of the symptoms varied from time to time, and there were marked periods of remission. The disease began in the intrinsic ocular muscles; ptosis, with or without diplopia, being usually the first symptom. Then the muscles connected with speech and deglutition were affected, and the upper and lower extremities were sooner or later involved. The affection differed markedly from bulbar paralysis of organic origin, in that in asthenic bulbar paralysis there was never muscular atrophy, even in the tongue, nor were fibrillary muscular twitchings observed. There was no complete paralysis of the muscles of the lip. In true bulbar paralysis there was seldom involvement of the third nerve, of the lower facial, or the minor branch of the fifth. The speaker called attention to the liability of mistaking asthenic bulbar paralysis for hysteria in the early stages. The pathology of the disease was regarded by all writers as infectious in character, and in none of the fifteen autopsies which had been made had any lesion been found in the nervous system. The case reported exhibited typically the essential features of the disease. The patient was thirty-seven years of age, married, and had six children. The disease developed after an attack of typhoid fever. There was marked ptosis of both eyes, more especially the left, with almost complete paralysis of the left external rectus and partial paralysis of the left superior rectus. There was difficulty in deglutition; the speech was markedly affected; the gait was awkward and shuffling, and after exertion both the arms and legs became much worse. After speaking for a short time the speech was much more indistinct and nasal, and in eating, after chewing and swallowing for a short time, deglutition was difficult. There were no sensory changes, no atrophy, and no fibrillary tremor. A feature of the case, to which the writer called especial attention as bearing upon the pathology, was the fact that two brothers of the patient had nystagmus with rotary tremor of the head, and that two of her own children had precisely the same condition.

**Asthenic Bulbar Paralysis.**—This was a case reported by Dr. John Punton, of Kansas City. The patient was a woman twenty-five years of age. The symptoms were of three years' duration. Among the first manifestations were general muscular weakness, diplopia, ptosis of the left eye, difficult mastication and deglutition, impaired articulation with nasal tone of voice, and paralysis of the soft palate. Two years later there were ptosis of the right eye, restricted movement in all directions of both eyeballs, and paresis of facial muscles. Her weight had decreased from one hundred and fifty-three pounds to one hundred and six pounds. All of the earlier symptoms had become aggravated. There was neither atrophy, nor tremor, nor fibrillary twitching in any of the muscles involved. Sensory symptoms were absent. Electrical irritability of muscles was normal. He considered the condition as a purely motorial defect.

Dr. Collins expressed the view that the disease was one of the motor-nerve system. There was very little in the clinical manifestations of the disease to prompt him to take it out of the domain of the sympathetic nervous system. Its phenomena were manifested largely through the motor system, but its most important symptomatology was due to trouble in the sympathetic system. In all probability there was some poison or infectious material continuously operative upon the vegetative portion of the body, that manifested its destructive effect periodically, whenever the vitality was sufficiently low to allow the poison to get the upper hand.

Dr. William G. Spiller, of Philadelphia, considered the symptom of fatigue as a very important element in this disease. In Dr. Punton's case that element was not nearly so prominent as in that of Dr. Sinkler. He therefore suspected that it might be a case of pseudo-bulbar paralysis. He thought that point should be carefully considered, for it was possible that there were regions of softening scattered about that might cause the symptom complex described.

Dr. H. M. Thomas, of Baltimore, said he had had a patient under observation for two years, who seemed to be in the early stages of this disease. There was no definite paralysis of the motor nerves of the eye, nor of the muscles of the face when the patient had rested. In the morning she was in pretty good condition. She could speak fairly well for a half-hour, when her voice gave out, and when she began to eat breakfast she ate well enough at first until she had masticated for a few minutes, when eating became progressively difficult.

Dr. Punton in closing said that the question of syphilis was very carefully considered in his case, and also the question of pseudo-bulbar paralysis, and he came to the conclusion that the case did not belong to that class, so there was nothing else to call it but asthenic bulbar paralysis.

---

*Second Day—Thursday, June 15th.*

**Hemorrhagic Pachymeningitis.**—Drs. Charles W. Burr and Daniel J. McCarthy, of Philadelphia, reported a case of hemorrhagic pachymeningitis, external and internal, of the convexity and cord, in a patient with multiple tuberculous tumors. This patient was a laborer forty-one years of age, who after a convulsion developed a left hemiplegia. Bulbar symptoms followed. Headache, vomiting, and double optic neuritis were present. Death occurred from tuberculosis. In the light of the pathological report, the bulbar symptoms were of central origin and due to the

pachymeningitis on either side of the convexity. The etiology was of interest on account of the presence of tuberculosis.

**Purulent Encephalitis.**—Dr. Guy Hinsdale, of Philadelphia, exhibited a brain showing purulent encephalitis and cerebral abscess due to infection through the umbilicus in a new-born child. The mother had a painful pregnancy, and after labor lasting forty hours pus from the uterus followed the placenta. The child died on the thirteenth day, after symptoms of meningitis. All the surfaces of the cerebrum and cerebellum were covered with a fibro-purulent exudate; a pus cavity was in the left anterior lobe and a large hemorrhage in the right. There were innumerable hemorrhages through the cortex with destruction of the infiltrated nervous tissue. The bacteriological examination showed a pathogenic organism corresponding in its description with the colon group, probably the bacillus coli immobilis.

**Muscular Dystrophy.**—Dr. William G. Spiller, of Philadelphia, read a paper on this subject and reported two cases with necropsy. One of these was of the facio-scapulo-humeral type and had been reported clinically by Duchenne, of Boulogne, Landouzy and Dejerine. The other case was also from the service of Dr. Dejerine, and in this patient the muscular atrophy began in the lower limbs. An examination of the tissues in these cases had been made microscopically by Dr. Spiller. The mother and elder brother of the first patient had muscular atrophy. In the patient the alteration in the muscles of the face was said by the mother to have begun when the boy was three years old, and the atrophy at that time was quite rapid. Muscular atrophy was seen in the trunk and lower limbs when the patient was five years old, and was seen in the upper limbs between the sixth and seventh years. Duchenne, of Boulogne, saw the boy in 1868 for the first time, when the latter was nine years old, and the face then presented the character so well described later by Landouzy and Dejerine. Contractures of all the limbs became very great before death. A necropsy made on this patient when he was about thirty-three years of age showed intense muscular atrophy, involving also the facial muscles except those of the eyes and the muscles of mastication. The central and peripheral nervous system was normal. The muscular atrophy in the second case was not hereditary. It began quite acutely in the lower limbs when the boy was eight years old, and extended to the trunk and upper limbs, and the patient became almost completely paralyzed in the trunk and extremities. The patient died at the Bicêtre, Paris, at the age of twenty years. The muscles were found to be intensely atrophied.

Dr. Spiller discussed the subject of muscular atrophy in general, and gave as his conclusions: (1) That cases of muscular atrophy occurred which presented the well-known localizations regarded as characteristic of the different forms of muscular dystrophy. In the large majority of these cases the spinal cord and peripheral nerves were normal. (2) In other rare cases presenting the clinical features of muscular dystrophy the nervous system was more or less involved. (3) The histological changes in the muscles were not pathognomonic of any form of atrophy. (4) It was proper to regard muscular dystrophy as a disease usually distinct from spinal muscular atrophy, but transitional forms connected the myopathic and myelopathic types of atrophy.

Dr. Thomas said that there had been many essays written upon this subject, trying to bring together all the cases of muscular dystrophy and atrophy, but he believed it would be necessary to wait for further investigation before anything more could be done than Dr. Spiller had pointed to in his conclusions.

**Subdural Hemorrhage.**—Dr. G. M. Hammond, of New York, briefly reported a case of subdural hemorrhage causing partial word-deafness, in which there was a marked inability to name objects and persons. The site of the lesion, which was of traumatic origin, was disclosed by a surgical operation.

**Motor Aphasia.**—This paper was by Drs. B. Onuf and T. Fränkel, of New York. It was based upon an analysis of one hundred and three autopsies reported in medical literature. It was claimed that the evidence was strongly against the view that the pathway went directly from Broca's centre to the bulbar nerve nuclei. It was probable that the insula participated in the function of speech in a similar manner as did Broca's centre. Attention was also called to a test used by them to demonstrate the preservation or abolition of internal language, and which was believed to be important for the distinction between cortical and subcortical motor aphasia, especially in illiterate persons.

**Anomia and Paranomia.**—This paper, "with some considerations regarding a naming-centre in the temporal lobe," was read by Dr. Charles K. Mills, of Philadelphia. The details of the case of a man who was unable to recognize objects by sight, hearing, touch, taste, and smell were first given. The patient, after an apoplectic seizure, developed a peculiar form of aphasia, apparently without any preceding paralysis or any other symptoms of focal lesion like visual blindness, hemianopsia, etc. When examined about nine years after the onset of the aphasia he had almost complete inability to name persons and objects which he was able to recognize through all his special senses. He had also a marked form of paralexia or paranomia. When he attempted to read, although he understood what he was reading, he repeated an absurd formula of a few phrases. He had limited spontaneous speech, even using short sentences without concrete nouns correctly. He could write many single words correctly, sometimes misspelling, however. He held his pen or pencil correctly and wrote such words as he did write with ease and firmness. He was not a motor agraphic. He was not word-blind nor letter-blind. He could not repeat a few letters (w, x, l). While the case was one of optic aphasia, it was in reality more than this. Dr. Mills believed that the evidence was sufficient to warrant the view that destruction of a region more or less concentrated or diffused, and probably mid-temporal in location, would cause the phenomena observed in cases of anomia and paranomia. While this was true, it did not follow that these speech disturbances could not be produced by lesions in other locations. Most of the regions destruction of which would lead to inability to name persons and objects had been summarized by Bramwell. Inability to name objects and persons might be due to (*a*) destruction of the "naming"-centre, (*b*) destruction of the nerve fibres which passed from that "naming"-centre to the motor-vocal speech centre, or (*c*) destruction of the motor-vocal speech centre by which these impulses were emitted. To this enumeration he would add that anomia or paranomia with associated phenomena would also be produced by destruction of the sensory percept centres and tracts leading from these centres to the naming or concept centre.

Dr. Collins, of New York, said that Dr. Hammond's case absolutely contradicted the existence of a special naming-centre, for here we had a lesion of the temporal convolution, just in the location where the auditory percipient and the memorizing centre were concerned. The case that Dr. Mills reported was absolutely parallel to Dr. Hammond's case. He did not deny that there was a naming-centre, but he did deny the position of a special naming-centre in the posterior part of the third temporal convolution. There was no fixed

position to which the name "naming-centre" could in every case be given.

Dr. E. D. Fisher, of New York, could see no reason why one should expect to find such a fixed centre.

Dr. Spiller agreed with Dr. Onuf that the word subcortical must be given up, for it could not be consistently used at the present day.

Dr. Knapp was unwilling to accept Dr. Mills' "naming-centre," and objected to the opinion brought forward by Drs. Hammond and Collins on the strength of the case reported. The general experience with traumatic injury of the brain was that one could not be certain of the lesion by considering it through a trephine opening. If there was a "writing-centre," as he believed, it was the last stage in the evolution of speech, and of course did not exist in a great number of people, for only a small number of the human race were able to write at all, and in a very large proportion of the illiterate it took all the muscles of the body to assist in writing.

Dr. Hammond said that in this case a piece of bone of sufficient size to expose completely the fissure of Sylvius and the brain tissue about it had been removed. Here was a well-marked case with a very definite lesion, and the man had anomia pure and simple. It seemed to him that in this particular case the irritation of the naming-centre was clearly defined, but it did not prove that the naming-centre need be in that position in every case.

Dr. Onuf also held the opinion that one could not speak of a naming-centre, for the function of naming an object was not a function of one region of the brain, but several centres participated in it.

Dr. Mills, in closing the discussion, said that even his friends who opposed him were coming to the point of view that there was a naming-centre. The only difference seemed to be that they had half a dozen naming-centres. Bramwell said it was a component part of the auditory centre. Just so long as there were concepts that could be recognized, just so long must there be other centres than the auditory centre for the recognition of them. This region was a higher evolution of the zone of language, and had been formed in the process of evolution.

**Anniversary Address.**—Dr. Wharton Sinkler, of Philadelphia, delivered an address commemorative of the twenty-fifth anniversary of the association. He called attention to the fact that the American Neurological Association was the third of the national associations which had been organized. At the time of its formation, there were but two neurological associations in Europe, both being in Germany. The first meeting was held in New York, June 2, 1875. Dr. Jewell, of Chicago, was the first president. There were thirty-five original members, and the limit of membership was fixed at fifty. A few years ago, the limit was increased to one hundred, and at the present time there were ninety-seven members. After speaking of the advances made in neurological science during this period, and referring especially to the advance made in cerebral and spinal localization by American neurologists, he concluded with a list of books and monographs contributed by members of the association.

**Facial Paralysis of Unusual Distribution.**—Dr. F. W. Langdon, of Cincinnati, read a paper illustrated with diagrams and photographs from a case of congenital, unilateral facial paralysis of unique distribution. On the left side there was total absence of action in the occipito-frontalis, pyramidalis nasi, levator labii superioris alæque nasi, levator labii superioris and risorius; the orbicularis palpebrarum was absent in its mesial half only. The eye could not be closed owing to this defect. The oral group of muscles, except the risorius, acted well, but less vigorously than on the healthy side. Neither contracture nor reaction of degeneration was present. There was corneal opacity resulting from the lagophthalmos. The congenital nature of the paralysis was evidenced by a clear history. No instruments were used at birth, nor was there any evidence of ear disease or defect of hearing or taste. Electrical treatment had produced only slight improvement in the lagophthalmos.

Dr. W. M. Leszynsky, of New York, said he had recently under his observation a patient in whom there had been facial paralysis involving all branches, and recovery had occurred in all except the orbicularis palpebrarum, which was usually the first muscle to recover its motility. He thought that Dr. Langdon's case, if not of congenital origin, might be looked upon as one of those cases in which a partial recovery had taken place. Several years ago he had reported two cases in which peripheral facial paralysis had existed for two years and yet the faradic irritability was preserved in the paralyzed muscles.

Dr. Thomas said that one could readily suppose, as had been said, that this was a case of facial paralysis in which recovery had not occurred.

**Sensory Disturbances in Epilepsy and Hysteria.**—This was the title of a paper by Dr. E. D. Fisher, of New York. He said that in both conditions hemianæsthesia might be present, but it was more frequent in hysteria. General or bilateral anæsthesia was not uncommon. He found this condition often existing independently of any seizures, and reported two cases. The first was that of a woman aged seventeen years. She had a history of true epileptic seizures since her first menstrual period three years previously. Examination showed complete anæsthesia of all forms of sensation over the middle of the forehead, both shoulders, the dorsal surface of both hands, and the extensor surface of forearms. The second case was that of a woman twenty-four years of age. A diagnosis of hysteria was made. There was anæsthesia of both shoulders, dorsal surface of the hands, and extensor surface of the forearms. In both cases the condition was permanent and probably of cerebral origin. It was evidently not of peripheral origin. In view of these cases and the literature on the subject, it would be well to examine for sensory symptoms in all cases of epilepsy.

Dr. Knapp said he had occasionally noted the presence of such sensory disturbances in epileptics, when it seemed pretty clear that the attacks were of epileptic character. In hysteria, he thought more would probably be found if a careful comparative test of the sensibility of the two sides was made.

Dr. Fisher in closing said that in these cases it was probable that some central nervous disturbance was concerned.

**Hæmatomyelia.**—Dr. James Hendrie Lloyd, of Philadelphia, read a paper on "Hæmatomyelia and Other Traumatic Affections of the Cervical Region of the Spinal Cord, including a Case Simulating Syringomyelia." The principal case was that of a man who had received severe injuries to the cervical spine many years before his death, and who had developed paraplegia with exaggerated reflexes but without involvement of the sphincters; there was atrophy with fibrillations of the muscles of the shoulders and upper limbs; and the dissociation symptom of syringomyelia was confined to one side. The lesion was found to be a necrosis involving largely the gray matter, caused by a fracture of the spine. Dr. Lloyd, therefore, concluded from observation of this case that the fibres for tactile sense passed in the posterior columns on the side of entrance of the sensory neuron, but that the fibres for pain and temperature entered the gray matter and passed to the opposite side, and then up through the antero-lateral column. The speaker also reported

a case of hæmatomyelia, in which the hemorrhage was largely in the anterior part of the posterior columns, involving slightly the posterior horns in the cervical region. The patient had lived nine days and had symptoms of a complete transverse lesion, except that the knee jerks were not involved.

Dr. Spiller exhibited microscopic sections from this case showing that the lesion commenced in the sixth cervical segment in the posterior column. There were considerable necrotic tissue with cell infiltration and a large number of swollen axis cylinders. The nerve cells in the area of greatest degeneration showed distinct chromatolysis.

Dr. H. T. Patrick thought these injuries to the cervical portion of the cord without fracture were not very rare, as he had seen several of them. He advised against operation, believing that the lesion was in the substance of the cord, and the subsequent course of these cases seemed to justify his conclusion.

Dr. Onuf had observed a patient with fracture of the lumbar vertebræ and complete paraplegia; but sensation was preserved in one extremity, and in the other it was preserved in the thigh but was completely absent in the foot and leg. The patient made a partial recovery.

**Landry's Paralysis.**—This was the title of a paper by Drs. Philip Coombs Knapp and John Jenks Thomas, of Boston. They stated that Landry's paralysis was now recognized as an acute parenchymatous degeneration of the peripheral motor neuron of toxic infectious origin. A few cases had recently been reported, in which, even by modern methods, no changes had been found. Three cases were given. The first patient was a young woman who was suddenly attacked with weakness and later complete paralysis of the legs, extending to the arms, eyes, and throat with some involvement of the sphincters, slight sensory disturbances, loss of reflexes, and diminished reaction to faradism. She died in fifteen days. The autopsy showed degeneration of the ganglion cells in the anterior horns, of the anterior and posterior roots, and of the peripheral nerves. The second patient was a man suddenly attacked with weakness of the legs, increasing to paralysis, extending to the abdominal muscles, the arms, and the left side of the face, with loss of reflexes, sensory disturbances, and loss of control of the sphincters. He made a partial recovery, with marked muscular atrophy. The third patient was suddenly attacked with weakness of the legs, increasing to paralysis and extending to the abdominal and respiratory muscles, and the muscles of the face, jaws, and throat, with loss of reflexes and some atrophy. He recovered completely.

Dr. Langdon had recently seen this disease in a man in whom the early symptoms were numbness in the upper extremities and slight interference with respiration. There was a distinct alcoholic history. Death occurred after a few days' illness.

**The Arrangement and Function of the Cell Groups in the Sacral Region of the Spinal Cord.**—Dr. B. Onuf, of Brooklyn, presented this subject by demonstration of diagrammatic charts. He explained that the various cell groups enumerated were not represented at all levels of the sacral cord, some of them extending only through one or two segments. They were distributed so typically that by studying their arrangement in a given section one could define rather exactly the level from which such segment was taken. Regarding the function of the various cell groups the following conclusions were drawn: The antero-lateral, postero-lateral, and post-postero-lateral groups presided probably over the muscles of the lower extremities. The antero-mesial group evidently supplied the very lowest division of the back muscles. The postero-mesial group probably was destined for the perineal muscles, including the sphincters of the rectum and bladder.

**Internal Hemorrhagic Pachymeningitis.**—Drs. William G. Spiller and D. J. McCarthy, of Philadelphia, reported such a condition occurring in a child nine years of age, with changes in the nerve cells throughout the central nervous system. The child was an idiot. She had never had convulsions and was not paralyzed, but presented signs of rachitis and congenital syphilis. About a year previous to her death she began to emaciate, and this emaciation became extreme. At the necropsy, a new membrane was found adherent to the under surface of the dura over the entire convexity of the cerebrum, and two or three ounces of fluid blood escaped when the membranes were incised on the left side. Comparatively little attention had been paid to the existence of internal hemorrhagic pachymeningitis in children, and no case in a child as old as the one reported was on record. Several writers spoke of the condition as occurring in early infancy. The authors found that intradural hemorrhage produced in animals led to the formation of an intradural vascular membrane, and these experiments convinced them that one cause of internal hemorrhagic pachymeningitis might be intradural clot. The changes in the nerve cells consisted of tumefaction and chromatolysis. Motor paralysis had not been observed during life, notwithstanding the existence of these cellular alterations, and these findings confirmed the view now held by some, that changes in the chromophilic elements of the nerve cell were not necessarily indicative of disturbed function. The theory of a reticular structure of the nerve cell was also discussed, and the existence of such a structure visible in the cells in their case was noted.

Dr. Fisher said that pachymeningitis hemorrhagica was quite prevalent in the almshouses. In children the hemorrhage was probably due to rupture of the thin-walled vessels.

Dr. McCarthy explained that the etiology of the case was rather obscure, there being evidence both of otitis and syphilis. For a short time before death there was a severe intestinal diarrhœa, but that probably had no causative relation to the presence of the membrane itself.

Dr. Spiller, in closing the discussion, said these cases were not so uncommon in the insane, but they were uncommon in childhood. So far as he knew, there was no other case reported as occurring in a child about nine years of age, though there were cases reported at an earlier age.

Dr. McCarthy said that the statistics showed that ten per cent. of the entire number of cases occurred during the first year of life.

**Election of Officers.**—*President*, Dr. E. D. Fisher, of New York; *First Vice-President*, Dr. Morton Prince, of Boston; *Second Vice-President*, Dr. J. W. Putnam, of Buffalo; *Council*, Drs. J. H. Lloyd, of Philadelphia, and J. Collins, of New York; *Secretary and Treasurer*, Dr. G. M. Hammond, of New York.

---

**Tachycardia.**—(1) Treatment of attack: Complete repose. Place the patient on the right side with head lowered to avoid fainting. Spray the precordial region and the back of neck near vertebra prominens, with chloride of methyl. Morphine and antipyretics give good results; digitalis is often of no use. If syncope is imminent give hypodermic injections of caffeine and ether. (2) Treatment between attacks: Discontinue the use of coffee, liquors, and tobacco if the patient be addicted to them; make the invalid avoid all mental and physical overwork. Prescribe prolonged use of arsenic, and for arterial hypotension administer quinine, ergot, or ergotin.—*Cincinnati Lancet Clinic*, March 4th.

# Correspondence.

## OUR LONDON LETTER.

(From our Special Correspondent.)

HAFFKINE'S PROTECTIVE INOCULATION, CHOLERA, PLAGUE, TYPHOID—MOORFIELDS HOSPITAL—INJUSTICE TO A SCOTCH PRACTITIONER—WOMEN'S INTERNATIONAL CONGRESS—DR. BOND'S SUSPENSION—EPILEPTIC COLONIES—BAZAAR.

LONDON, June 30, 1899.

THE important investigations carried out in India by Mr. W. M. Haffkine, C.I.E., lend additional interest to the lecture he delivered lately before the Royal Society on preventive inoculation. His methods were lucidly described and the results stated without any effort to produce effects; in fact, the true scientific spirit was manifest throughout. At the outset Mr. Haffkine observed that the immediate effect of a given virus or its derivate differs with the kind of virus, the process of modification it has been submitted to, and the species of animal to which it is applied. As an example the Indian monkeys (gray or brown) are very susceptible to plague virus, as also are rabbits and guinea-pigs; but the horse is not affected. But if the microbes in a plague culture are killed by heat, the relations of monkey and horse seem to be reversed; the guinea-pig becomes scarcely susceptible to large doses, but the rabbit remains so. There are animals in which inoculation leaves no lasting effect, others in which a temporary immunity is set up, others in which susceptibility seems increased, others in which great and lasting immunity is produced. Again, the study of anti-cholera inoculation in India shows that while the absolute number of cases and deaths is strikingly decreased, the proportion of deaths to those attacked is not affected. This is in accord with laboratory experiments which tend to show that immunity against the living microbe may differ from that due to its products. Mr. Haffkine endeavored in his anti-plague virus to combine if possible a reduction of attacks with a lower case mortality by treating the system with the bodies of the microbe as well as their concentrated products. The effect of his prophylactic having been worked out on animals and the absolute harmlessness of the inoculation having been demonstrated on man, comparative tests were carried out on a larger scale. At the Byeulla jail epidemic one hundred and fifty-four prisoners volunteered and were inoculated, one hundred and eighty-three remaining without the treatment. For seven days (except the fourth) after the inoculation cases occurred among the uninoculated—twelve cases and six deaths. In the inoculated group one case occurred next day in which the patient rapidly recovered, and one on the last day, in which also recovery occurred. From these figures it was seen that inoculation was useful in a localized, already existing epidemic extending over seven days. The next trial was made in the Umerkadi jail, Bombay, where plague broke out at the end of December, 1897, and by January 1, 1898, three cases occurred, all fatal, and fatal cases occurred for thirty days. On January 1st half the prisoners were inoculated, and all continued in exactly the same circumstances. Some of each group were discharged, and thus their cases were removed from observation. The average daily strength of those in jail to the end was: uninoculated, one hundred and twenty-seven; inoculated, one hundred and forty-seven. In the former ten cases occurred, six being fatal; in the one hundred and forty-seven inoculated three cases occurred, and all recovered. In the third jail (Dharwar) five fatal cases occurred, and then all the prisoners, numbering three hundred and seventy-three, volunteered and were inoculated. One case occurred two days after the operation, and recovery took place. That was the only one.

Among the free population a remarkable experiment was carried out at the village of Undhera, where plague had carried off seventy-nine victims. Then inoculation was tried in seventy-one families, but not in sixty-four others. In the seventy-one there were eight cases with three deaths; in the sixty-four, twenty-seven cases with twenty-six deaths. Mr. Haffkine gave full details of these trials, as they were most precise. But there were also more extended trials among various populations devastated by plague, as in the Damion epidemic extending over four months and in the towns of Hubli, Dharwar, and Gadag, where some eighty thousand persons were inoculated. The difference in the mortality was estimated to be over eighty per cent., often approaching ninety, in favor of the inoculated. The case mortality of those treated in the larger hospitals was fifty per cent. less in those inoculated.

The question of the duration of immunity is unsettled, but Mr. Haffkine observed that for the present it may be said that the effect of inoculation lasts the length of one epidemic, which on the average extends over four to six months. The Indian government has recognized inoculation certificates as exempting the holders from plague rules for six months, with the understanding that if accurate data are forthcoming of the effect lasting longer they will be exchanged for other certificates without re-inoculation.

Having mentioned the further problems which are engaging the Bombay plague-research laboratory, Mr. Haffkine spoke in favor of the new campaign which has been inaugurated against typhoid fever. He pointed out the resistance of the microbe of this disease as compared with that of cholera. But he found circumstances in connection with both which led him to expect from typhoid inoculation in man a similar protective effect to that obtained by cholera inoculation. Should this prove to be so it will be a triumph of even greater importance to Europeans.

Moorfields is a name that at once calls up the thought of the great ophthalmic hospital of which the fame has gone forth into all countries. The old building became too straitened for its work, and removal was determined on. A site in the City Road was secured, and the Prince of Wales laid the foundation stone of the new hospital in 1897. On Tuesday last the Duke of York, accompanied by the Duchess, performed the ceremony of opening the new buildings. Moorfields has long been the resort of all ophthalmologists who visit London, and is likely to maintain its honorable position as a scene of important discovery and a school of ophthalmic medicine and surgery. As a hospital it is so famous that there is no doubt that at times it has been resorted to by many well able to pay. It is hoped that this abuse will in future be kept in check.

Sir C. Cameron, M.D. and M.P., has issued a pamphlet exposing a gross case of "the maladministration of justice in Scotland." The case is that of Dr. Lamont, who was a poor-law official in the Hebrides. His zeal and fidelity in the care of the poor have only brought him injury so gross that Sir Charles tried by questions in Parliament to obtain redress, but without success. An epidemic in an island in Dr. Lamont's district caused such a panic that the people would not attend the sick or place the dead in coffins. The Scottish government board after an inquiry into the epidemic censured the parish council, but at the same time praised Dr. Lamont. A few months later the council took its revenge and dismissed Dr. Lamont, who was afterward arrested on a charge con-

nected with vaccination work, but acquitted. Sir C. Cameron's history of the case will perhaps bring some redress, and should go far to convince Parliament that appointments should not be terminable by the mere will of a parish council.

The International Congress of Women has been sitting this week. On Tuesday the discussion was on "The Training and Qualifications of Women Doctors," opened by Dr. Sarah Stevenson from the United States. Another paper was on "Women's Work as Doctors in Hospitals and in Private Practice." To-day nursing is the subject under consideration. This congress seems to be an outcome from the women's whiskey war in the States some twenty-five years ago, which about eleven years ago led to the International Council of Women. The organization seems now to be very widespread and is giving considerable attention to medical and sanitary questions. Nine countries sent delegates, and representatives came from eight others. There were also seven vice-presidents from different countries.

The local government board has declined to indorse the suspension of the medical officer of health by the St. Olive's vestry which I lately reported. The origin of the matter was in the removal of bodies from the parish church, which had been superintended by the doctor. The vestry has been curtly told that the medical officer had not exceeded the duty imposed by Parliament on him in conjunction with the bishop and ecclesiastical commissioners.

The Duke and Duchess of York are keeping up the royal reputation for interest in our hospitals and other charities. On Saturday they went to Chalfont and opened four new homes in the colony which has been established there by the National Society for the Employment of Epileptics. The Duke is president of this useful society.

Charing Cross Hospital will benefit by the great bazaar at the Albert Hall to the amount of over £13,000, thus capping the Press Bazaar of last year by some £3,000.

## Medical Items.

**The Contagiousness of Leprosy.**—With respect to this point Mr. Jonathan Hutchinson says in his *Archives:* "In leper asylums the doctors, nurses, and servants never contract the disease. Inference, it is not contagious. When lepers are imported into countries where the disease does not prevail, as, for instance, from Norway into the United States, they never communicate the disease to others. Inference, it is not contagious. In further confirmation of the last proposition it may be stated that no year passes without the introduction into England of a certain number of lepers—Englishmen who have developed the disease abroad. In all the nature of the malady is carefully concealed, and they mix with their friends without any special precautions. No single instance of any suspicion of contagion has occurred."

**A Psycho-Physical Study of Colored Children.**—As the outcome of a special study of ninety-one colored children, Macdonald (*Journal of the American Medical Association*, May 27, 1899, p. 1,140) has determined that colored children are much more sensitive to heat than are white children, which probably means that their power of discrimination is much better, and not that they suffer more from heat. Colored girls have a larger circumference of head at all ages than white girls. White children not only have a greater standing height than colored children, but their sitting height is still greater; yet colored children have a greater weight than white children, as white children relative to their height are longer-bodied than colored children. The percentage of long-headedness—dolichocephaly—among colored boys is more than double that of white boys. This may be due to racial influences.

**Prof. Ewart on Zebras.**—At the Royal Institution recently Prof. J. Cossar Ewart began the third and last of his lectures on "Zebras and Zebra Hybrids" by describing the various types of zebra that occupied East Africa, and pointing out how they differed in the arrangement and width of stripes, the form of the hoof, the length of the ears, etc. Westward a still greater variety was found, including the typical Burchell zebra, which differed from others in having white legs and very few stripes on the shoulders. From this animal it was only a step to the extinct quagga, which he thought might be regarded as the one effort of the African continent to form a true horse. The interest in these animals lay in the fact that they illustrated an enormous amount of variation, an amount scarcely to be expected in a group of wild animals in so limited an area. Discussing this circumstance, he found reason to doubt some prevailing views about heredity, and quoted instances to show that owing to prepotency in one of the parents intercrossing did not always lead to swamping. As to the use of zebras, he said they were sometimes perfectly docile. But even the quietest, if they imagined something was going to leap upon them, would make a bound which was quite uncontrollable, and unless they could be educated out of that habit he did not think they were likely to be of much service to man. The immunity of the zebra from the tsetse-fly disease had been taken for granted, but no experiments had been made to prove the immunity alleged. The probability was that zebras living in a fly country were immune, but not others.

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ending July 15, 1899:

### A REPORT OF TWELVE CASES OF PROSTATIC HYPERTROPHY BENEFITED BY THE BOTTINI OPERATION, WITH A FEW COMMENTS AND SUGGESTIONS.[1]

BY RAMON GUITÉRAS, M.D.,

NEW YORK.

SOME time ago I published an article in the *New York Medical Journal*, entitled "The Technique of the Bottini Operation," for the purpose of giving some of the minor details connected with this procedure, which are important in an operation that has to be performed so rapidly.

In looking up the literature of the subject, I was surprised to see how many cases were referred to, and yet how few in comparison had been systematically reported.

It was accordingly with regret that I looked over the meagre statistics of the cases upon which I had operated and felt that they were not worth reporting. The results, however, were so good that I have decided to do so, at the same time feeling that I should make a plea to my colleagues to be more careful in their own observations than I have been, in order to produce records which will be more interesting and instructive. The cases that I shall report are twelve in number, the patients ranging in age from forty-nine to seventy-nine years. They were all in fair physical condition at the time of the operation, and I might consider some of them cured if I felt certain that the improvement they have already shown would continue. The reason why I was not more careful in my records was because I was rather sceptical concerning the good results that were claimed for the operation, and felt that I was trying a procedure which was painted more brightly than it deserved to be. So far, however, my cases have progressed very favorably, and I have been more than pleased with the appearance of the patients that I have treated.

The report of these cases is as follows:

CASE I.—Captain, aged sixty-five years, tall, of slender build, looking pale and cachectic. The patient was suffering from almost complete retention and had not been able to pass any urine for several months, excepting a few drops in the morning. He had been broken into catheter life and used his instrument regularly three times a day.

Examination: Palpation of kidneys, negative. Suprapubic examination was also negative, as the patient did not have much urine in his bladder at the time of the examination. His external genitals were normal and of medium size. Rectal examination of internal genitals showed the prostate to be only slightly enlarged and of ordinary consistence. Seminal vesicles, negative. The urethral examination showed an impediment at seven inches, but a slight push sent a No. 14 straight soft-rubber catheter through. The remainder of the canal was of good calibre. Seven and one-half ounces of urine were withdrawn, which represented that part of the residual urine in the bladder at the time. The urine escaping through the catheter came away with considerable force, indicating that the tone of the bladder wall was good.

The report of the analysis of the urine made by Dr. George Blanchard was: Pale, turbid; specific gravity, 1.013; albumin, trace; sugar, none; urea, 1.3 gm. to litre; sediment, large quantity of pus with mucus and some bladder epithelium, and many bacteria.

Operation: The bladder was washed through the catheter until the washings came away clean. One ounce of a three-per-cent. solution of eucaine was then injected into the bladder and along the urethra. The usual six ounces of boric-acid solution were then injected and allowed to remain. The incisor was then immediately introduced and stuck in the prostatic urethra. Elevation of the hips on a sand bag and a sudden pushing in of the instrument, while the handle was depressed, made it enter the bladder. The forefinger of the left hand was then inserted into the rectum and placed on the margin of the base of the prostate, and the incisor was drawn forward until its beak was over the end of the finger in the rectum. Three incisions were then made: (1) Posterior 3 cm. long; time two minutes; current 37½ amperes. (2) Right lobe 2¼ cm. long; time one and one-quarter minutes. (3) Left lobe, same.

The patient said that he felt very little pain while being operated upon. At 9 P.M. he had not passed any urine since the operation. He was accordingly catheterized, and the catheter allowed to remain. The patient passed a comfortable night; no elevation of temperature; pulse normal. The urine drained away clear.

This patient was operated upon out of town, and I did not see him for some time afterward. The report of the attending physician two weeks afterward was as follows: "The patient made a rapid and complete recovery; suffered no shock. Highest temperature, 99° F.; highest pulse rate, 70. He now passes from one and one-half to three pints of urine in the twenty-four hours, from two to four ounces at a time. In spite of this quantity voided, there still remains between one-half pint and one pint to be withdrawn by catheter morning and evening. One piece of blood clot was passed five days ago, and several pieces of prostatic tissue this morning, since which he has urinated more freely than at any time." A report two weeks later from the doctor stated that the patient had been passing blood in his urine and that a few drops came away after urinating. On a subsequent visit I cystoscoped the patient, but the manipulation of the instrument increased the bleeding and obscured the field to such an extent that the examination revealed nothing. It seemed probable that the bleeding was due to granulations at the seat of the prostatic incisions. Instillations of nitrate of silver were ordered, since which time no report of the case has been received.

Note: The report of this case shows marked improvement, as from an almost complete retention he has been brought into a condition in which he can pass from twenty-four to forty-eight ounces of urine a day voluntarily. I think that the reason why he still has some residual urine is because in making the incision I drew out the instrument until its beak in the bladder

[1] Read before the New York Academy of Medicine, May 9, 1899.

was just over the tip of the rectal forefinger at the margin of the base of the prostate, and that probably in drawing it forward to this point it was brought beyond the vesical margin of the base of the gland, which probably extended back farther than the rectal base. In this case the incision was not begun precisely at the vesical base of the gland, but a little in front of it, thus allowing some obstruction to remain. The bleeding, I think, has been caused by the frequent catheterization since the operation, which has irritated the prostatic urethra, during the time that the sloughs were being thrown off, sufficiently to cause the formation of granulation tissue. I think that this is a case for a second operation.

Case II.—Sea captain, aged fifty-eight years, short, well-nourished, of limited intelligence. Patient has been troubled for some months with frequency of urination during the day and night, and dribbling (incontinence).

Examination: Kidneys negative; external genitals normal. Rectal examination showed the right lobe of the prostate to be normal and the left to be about one-half inch longer than the right; seminal vesicles were not felt. Urethral examination showed the meatus to be contracted, admitting only a No. 16 French coudé catheter, which passed through the remainder of the urethra into the bladder. There were two ounces of residual urine present.

The report of the urinary analysis made by Dr. George W. Blanchard was: Urine turbid, pale yellow; specific gravity, 1.018; trace of albumin; no sugar; urea, 1.8 gm. to litre. Sediment, large amount of pus; mucus; bladder epithelium in large amount; few prostatic cells; many bacteria.

Operation: The patient's bladder was anæsthetized with a three-per-cent. solution of eucaine, and the regular amount of boric acid (six ounces) was injected. It was found that the meatus would not admit the incisor, and accordingly it had to be cut up to a sufficient size to allow the instrument to enter. Much difficulty was encountered in passing the incisor through the prostatic urethra, which imparted the feeling of extreme hardness. This was accomplished, however, after putting a support under the sacrum. The finger in the rectum gave the patient considerable discomfort and caused him to close his thighs so tightly that it was almost impossible to feel the base of the prostate. Three incisions were made: Posterior, 3 cm. long, time two minutes, current 40 amperes; anterior, 2 cm. long, time one minute, current 40 amperes. At this juncture the water in the cooler gave out, and the operation had to be postponed until the reservoir could again be filled. The current of electricity was immediately shut off, but by this time the effect of the eucaine had evidently worn off. Notwithstanding this, the third incision was made as follows: Left lobe, 3 cm. long; time two minutes; current 44 amperes.

The patient felt dizzy after the operation. He was put on benzoic acid, gr. xv. t.i.d., and instructed to drink plenty of water. On the evening of the operation his temperature was normal and pulse 60. He passed urine during the night without difficulty.

The physician's report two weeks later was as follows: "The patient made a good recovery. He had a slight chill on the first attempt to pass urine after the operation, which was followed by a rise of temperature to 100.2° F. His dribbling, of which he complained greatly before the operation, has entirely ceased, and he has but three drachms of clear residual urine." Since then I have heard nothing more of the case, excepting that he still continues to improve.

Comment: This patient has certainly been very much benefited by the operation. His frequency of urination has been lessened; his dribbling has ceased, and he now has only three drachms of residual urine, which is not sufficient to cause much bladder disturbance. It was unfortunate that there were two causes of delay during the operation: the first, that of cutting the meatus, should have been anticipated by doing it at the time of the first examination; the second, that of the failure to fill the reservoir, was a matter of carelessness and shows the importance of seeing to every detail before the operation is begun.

Case III.—Ship-caulker, aged sixty-seven. Has the appearances of a hard-working man, rather slight and bowed with age, although his general condition was good for one of his years. His family history was negative. He had had a urethritis when a young man, but no other venereal trouble. Twelve years ago he had an attack of retention, but since then he has been able to urinate freely until his present trouble began. For three years past he has been suffering from frequency of urination, accompanied by pain and tenesmus. Three months before the operation he came to me for treatment, complaining of pain in the perineum and over the pubes, together with burning during micturition. He was passing his urine every two hours during the day and every hour during the night. I treated him with palliatives, antispasmodics, urinary antiseptics, and bladder irrigations, and for a while he was improved, but then relapsed again, and finally after three months of treatment he concluded to undergo an operation.

Examination before operation: His heart and lungs were normal. Palpation of his kidneys was negative. There was no suprapubic dulness. His external genitals were normal and well-formed.

Per rectum: His prostate did not seem to be enlarged, although the left lobe was somewhat longer than the right. His seminal vesicles could not be felt. There was no bladder tenderness.

Urethral examination showed an obstruction to a straight catheter at seven inches. The urethra up to this point was normal and of a size admitting a No. 28 French sound. A coudé catheter, No. 20 French, slipped into the bladder, and two ounces of residual urine were drawn off. The bladder was found capable of containing eight ounces, and its walls did not show any marked atonicity.

Urine examination made by Dr. Brooks, Post-Graduate Laboratory, showed it to be of light color, fairly clear, with a nebulous sediment; reaction acid, specific gravity 1.015. Small amount of albumin, no sugar.

Microscopical examination: A considerable amount of pus, a few blood cells, some round bladder epithelium, and some mucus threads. No crystals. Some bacteria were present.

This seemed to be a good case for operation; the patient's bladder had not suffered to any marked degree, and his kidneys were in good condition. On entering the hospital, his temperature was 98° F., his pulse 60. He was put on salol gr. x. t.i.d. and prepared for operation. He passed forty-eight ounces of urine.

Operation: This was performed under four-per-cent. eucaine anæsthesia, about half an ounce being used in the anterior and posterior urethra. Six ounces of boric-acid solution were injected into the bladder. A sandbag was placed under the hips to elevate the pelvis. Three incisions were made—one posterior and two lateral. (1) Posterior, 2¾ cm. long; time two and one-quarter minutes; current 45 amperes. (2) Left lateral, 2¼ cm. long; time two minutes; current 45 amperes. (3) Right lateral, 2 cm. long; time one and one-half minutes; current 45 amperes.

After operation: The patient did not suffer much pain during the operation. He did not attempt to pass water afterward, and was immediately put to bed. He had been cystoscoped on a previous occasion.

On the following day his temperature went up to 101.2° F., and for about a week it ranged from 98.4°

to 100.4° F. His pulse ranged from 68 to 90. When he left the hospital his temperature had been normal for several days.

| Date. | Temp. | | Pulse. | | Respiration. | Urine. Ounces. | Stools | |
|---|---|---|---|---|---|---|---|---|
| | P.M. | A.M. | A.M. | P.M. | | | | |
| | Degrees. | | | | | | | |
| 1st day. | .. | 98.3 | .. | 60 | 20 | | | |
| 2d day. | 98.0 | 100.6 | 75 | 80 | 18 | 56 | .. | He had slept well during the night, although he had a slight cough for which Stokes' expectorant mixture was given. Salol gr. x. t.i.d. was continued. |
| 3d day. | 98.6 | 100.0 | 84 | 88 | 20 | 31 | 1 | Saline purge given. Patient had slept well all night; he complained of pain over the pubes and perineum, although he had been passing his urine very frequently. As the amount had been only thirty-one ounces, a catheter was passed to see if his discomfort was due to an accumulation of urine in the bladder. Only about two ounces were drawn off (the regular amount of residual urine). |
| 4th day. | 98.2 | 99.0 | 76 | 89 | 18 | 40 | 2 | As he has been taking large quantities of water this did not seem to be sufficient, and he was accordingly put on a mixture containing sweet spirits of nitre, gtt. xv.; acetate potassium, gr. xv. t.i.d. |
| 5th day. | 98.0 | 98.4 | 78 | 80 | 20 | 32 | 1 | |

Result: The patient seems to be much improved. He urinates about every three hours during the day and three times during the night. Otherwise he feels better and more active. He complains principally of a burning feeling in the neck of the bladder. His residual urine has diminished to one-half an ounce. There is no obstruction to the passage of a straight catheter into his bladder. His urine is clear, there are no shreds; reaction acid; no albumin; microscopically, a little pus; no blood. There is still a small amount of bladder epithelium.

Note: The patient passed sloughs from the seventh to the last day, at which latter date he brought to the hospital a large slough three-fourths of an inch long and one-third of an inch wide, passed in perfectly clear urine. He is still on treatment. He drinks plenty of water. He takes belladonna and benzoate-of-sodium mixture t.i.d., and has his bladder washed out twice a week with a 1:4,000 nitrate-of-silver solution.

Case IV.—Machinist, aged sixty-five years. A man slightly above medium height, thin, nervous, and looking older than the age given.

The patient stated that he was well up to three years ago, when he began to suffer from frequent and precipitate urination, the act being accomplished after a good deal of straining toward the end. He said that he had at no time suffered any pain, although there was a feeling of heaviness in his perineum and some burning as the urine passed through his urethra. After these symptoms had continued for about a year, he consulted a physician, who told him that he could not empty his bladder and that he should catheterize himself twice a day. He accordingly started in on his catheter life, which he has continued up to date. During the last six months, as his condition has been growing worse rather than better, he has been in the habit of washing out his bladder once a day with a boric-acid solution. This relieved him somewhat at first, but he still urinates every hour during the day and every two hours during the night, and the act is attended by considerable straining and pain in the bladder and back. The patient also suffers from incontinence (dribbling), for which condition he wears a urinal.

Examination: Palpation of the kidneys reveals no enlargement, although there is some pain on pressure over the right organ. Suprapubic examination was negative. His external genitals are normal. Rectal examination shows the lateral lobes of the prostate to be elongated, the right being the longer. The seminal vesicles cannot be detected. Examination of the urethra shows it to be normal, barring the elongation and bulging of the prostatic portion. The amount of residual urine is seven ounces, the bladder capacity twelve ounces.

The report of the urinary analysis made by Dr. Brooks, Post-Graduate Laboratory, is: Color, amber; fetid; cloudy; reaction, alkaline; specific gravity, 1.016; albumin, trace; no sugar; pus abundant; few blood cells; bladder epithelium; no casts. Examination by the cystoscope showed the bladder wall to be dark red and congested. The inner border of the prostate could be clearly seen, and the middle lobe seemed to project quite prominently. There were no shreds or streamers hanging from the wall.

Operation: The bladder was washed out thoroughly, and an ounce of eucaine solution was injected into the urethra and bladder, after which eight ounces of boric acid were injected and allowed to remain. The patient was then brought into the lithotomy position, and the instrument inserted. Three incisions were made: (1) Posterior, 3 cm. long; time three minutes; current 40 amperes. (2) Right lobe, 2½ cm. long; time two and one-half minutes; current 40 amperes. (3) Left lobe, 2¼ cm. long; time two and one-quarter minutes; current 40 amperes. The latter part of the operation was clearly painful to the patient, as the effect of the eucaine had evidently worn off. Some whiskey and strychnine were accordingly given. The patient was put to bed and ordered to take urotropin gr. x., t.i.d., and to drink large quantities of water.

The remainder of his convalescence was normal. He was allowed to be up and about at the end of the week.

On the tenth day a number of sloughs were passed, one-fourth inch by three-fourths inch. On the twelfth day patient passed chunks of slough which almost blocked the urethra. One month after the operation patient had only one-half ounce of residual urine.

A report of this case later, coming from a competent surgeon with a well-equipped laboratory, was that the urine was normal, but that the patient was in a hysterical condition. The last time that I saw him he was very neurasthenic, and his urine was of low specific gravity, and showed a slight trace of albumin and some hyaline and fine granular casts.

Comment: This patient has certainly been much benefited by the operation, as his residual urine has been reduced in quantity from seven ounces to one-half ounce, and the tone of his bladder wall has been in a great measure restored.

It has taught me that the strain of an operation under a local anæsthetic is often considerable, and that

this, together with the preparatory purging which the patient has to undergo and the nervous tension under which he is before going upon the table, is sufficient to give him quite a shock.

Anything that postpones the operation after the eucaine has been injected, such as cystoscopy, the failure of water supply in the cooler, the cutting of the meatus, spasms of the vesical sphincter or cut-off muscle, allows the anæsthetic effect to wear off and thus causes the patient to suffer more, and consequently increases the danger of shock. Another interesting point is the question of nervous conditions arising here, as they do after other operative procedures for hypertrophied prostate.

Case V.—Railroad man, aged fifty-seven years. A tall, powerful man of healthy appearance.

History: No venereal history. Five years ago he began to have trouble in passing urine and was obliged to get up at night. He dribbled at times. Occasionally his urine stopped suddenly. He also has had a good deal of pain in the back and in the region of his bladder. Of late, his pain, frequency, and dribbling have continued to increase to such a degree that he decided to enter the hospital. He also has had chilly sensations for the last few days. The patient urinates eight or nine times a day and twelve or fourteen at night.

Examination: Palpation of kidneys, negative; suprapubic, negative; external genitals are large; varicocele on left side. Per rectum: Prostate large, hard, and sensitive; right lobe the larger; bladder, negative. Per urethram: Meatus small, admits a No. 23 French. The remainder of the urethra is free down to the prostatic portion, where a small straight catheter (18 French) encounters obstruction; a small soft-rubber coudé catheter enters and draws off two ounces of residual urine.

Report of urine (by junior assistant): Color, yellow; cloudy; odor, not pronounced; specific gravity, 1.025; chemically—reaction acid; albumin, a trace; no sugar. Microscopically—moderate number of pus cells.

Operation: Patient under local anæsthetic, three-per-cent. eucaine. Three incisions were made: (1) Posterior, 3 cm. long; time two minutes; current 45 amperes. (2) Anterior, 2 cm. long; time one and one-half minutes; current 45 amperes. (3) Right lobe, 2½ cm. long; time one and three-quarters minutes; current 45 amperes.

After operation: The patient suffered no immediate shock; he felt the pain very much.

| Date. | Temp. A.M. | Temp. P.M. | Pulse. | Respiration. | Urine. | Stools. | |
|---|---|---|---|---|---|---|---|
| | Degrees. | | | | | | |
| 1st day. | .. | 99.0 | 76 | 20 | | 1 | Operation performed at 2:30 P.M. |

| 3d day. | 98.0 | 98.2 | 84 | 22 | | 1 | Salol gr. x., t.i.d. The patient was kept on fluid diet for two days, and then, as there was no elevation of temperature, regular diet was given. Purge given. |
| 4th day. | 98.4 | 98.0 | 80 | 20 | No report of urine made. | | |
| 5th day. | 98.2 | 99.0 | 78 | 18 | | | |
| 6th day. | 99.3 | 98.2 | 82 | 24 | | | |
| 7th day. | 98.3 | 98.2 | 74 | 22 | | 2 | |

The patient was kept in bed for one week, after which he was allowed to be up and about. His recovery was uneventful. Shreds were passed from ten to eighteen days after the operation, at the expiration of which time he passed urine three or four times during the day and went from 9 P.M. to 5 A.M. without urinating. At the expiration of twenty-one days he passed urine five times during the day and four times during the night, accompanied by great straining and pain in the end of the penis. He then passed a clot of blood, which relieved him greatly. Belladonna and sodium benzoate mixture was ordered, and salol discontinued.

Twenty-four days after he is urinating five times a day and once at night; feels comfortable. One month after operation the condition is the same. Residual urine, one ounce.

Comment: This was certainly a good result. The patient then passed from under my observation, and I have not seen him since. An interesting point in this case is the fact that about three weeks after the operation, on examining the patient by rectum, I noticed a marked linear depression between the two lobes, and called the attention of the house staff to it, as the line of atrophy caused by the throwing off of the slough. On consulting the dictated history of the case, however, I found that the same groove had been detected on the first rectal examination.

Case VI.—Tailor, aged fifty-eight years. Tall and thin, looking pale and depressed.

History: Patient has been troubled with frequency of urination during the last year, not only during the day, but also at night. Sometimes he has had great difficulty in starting his stream, and on one occasion, six weeks ago, he had had an acute attack of retention, for the relief of which he had entered the hospital. This was easily relieved, and he was put on urinary antiseptics and antispasmodics. The rest in bed, combined with the use of these remedies, benefited him considerably. As the patient had been suffering from a hydrocele for a number of years, and was very desirous of having it cured, he took advantage of this stay in the hospital to be operated on. The operation was successful. When he left the hospital and began to work, the frequency of urination returned, accompanied by pain and burning. He urinated four or five times a day and five or six times at night.

Examination: Palpation of kidneys, negative. Suprapubic examination was also negative. The external genitals were normal, with the exception of the thickened feeling of the left testicle following the hydrocele operation. There was also a hernia on the same side. Rectal examination showed the whole of the prostate to be enlarged and hardened, the left lobe being the larger. The seminal vesicles were not felt. The urethra admitted a 24 straight French catheter down to the prostatic urethra. An elbowed catheter of a smaller size had to be used to enter the bladder, as there was a marked impediment at its entrance. There were two and one-half ounces of residual urine present. Examination for stone was negative.

Report of analysis of the urine (Brooks): Yellow; moderate nebulous sediment; no shreds; reaction neutral; specific gravity 1.015; albumin, a trace; sugar, negative; pus abundant in single cells and in groups; no crystals; epithelia, a few round bladder cells and caudate from the neck of the bladder; casts, hyaline, granular, and epithelial.

Operation: Bladder washed out until clear. One ounce of a four-per-cent. eucaine solution was injected into the bladder and the urethra. Patient was operated upon in the dorsal decubitus with the legs extended. Only one cut was made: Posterior, 3 cm. long; time two minutes; current 40 amperes. After the first incision was made, the current was turned off until the instrument was in position for the next incision. When it was in place, the current was again turned on, but the hand of the disk only registered 10 amperes, which was not sufficient to heat the blade; therefore the operation was discontinued.[1]

The patient remained in hospital for another week for the sake of a longer rest, during which period his temperature and pulse were normal. He passed the bulk of his sloughs on the eighth day. Two weeks after the operation the patient had two ounces of residual urine. This was thick and foul-smelling. The

[1] It is important to know that the battery contains only enough electricity for two or three operations.

belladonna and benzoate-of-sodium mixture was given. The patient has a good deal of burning and still some frequency. Advised him to keep up his irrigations until his cystitis was cured. The patient came very irregularly, however. One month after the operation he had but one-half ounce of residual urine.

| 7th day. | 97.8 | 97.2 | 86 | 24 | 52 | 2 | Slept well. |

Comment: Very interesting, as only one incision was made, and the result was good.

Case VII.—Tailor, aged forty-nine years. Medium height, black hair and beard, slightly bald, well-nourished.

History: Patient came from out of town for operation. He stated that he had been well up to four years ago, when, while bending over to pick up something from the floor, he had felt a cold sensation on the left side of the abdomen extending down into the groin. He had gone to a physician, who had treated him by passing sounds twice a week for a short time. After this he began to pass his urine frequently, both during the day and the night, and to have pains in his lumbar and inguinal regions. At present he passes urine every hour and a half, both day and night, and complains of pain in the perineum and over the pubes.

Examination: Lumbar and hypogastric percussion and palpation, negative; external genitals normal. Per rectum: The prostate is found to be markedly enlarged, especially on the left side; bladder tender, but nothing abnormal detected. Urethra free down to the prostatic portion, in which there is a marked impediment. Cystoscopy shows a chronic cystitis and an elevation of the base of the prostate. There were six ounces of residual urine.

Urinary analysis (Dr. Brooks): Yellow, foul odor, cloudy, acid; specific gravity, 1.015; albumin, trace; no sugar; moderate amount of pus; blood present; epithelia, squamous and round, from bladder; casts, few hyaline, granular, and epithelial.

Operation: When the patient came in for operation, it was found that his temperature was 103.6° F.; pulse, 110; respiration, 46. Examination showed that he was suffering from influenza with a "grippal" pneumonia of the right lung. This delayed the operation for ten days, as it was thought best to wait until his temperature had been normal for a few days. Three incisions were made: (1) Posterior, 3 cm. long; time two minutes; current 40 amperes. (2) Anterior, 2 cm. long; time one and one-half minutes; current 40 amperes. (3) Left lobe, 2½ cm. long; time one and three-quarters minutes; current 40 amperes. The patient was ordered ten grains of salol three times a day and instructed to drink plenty of water.

The patient's pulse and temperature were normal during the second week, so no record was kept. He passed sloughs from the eighth to the twelfth day. He called at the clinic two weeks after operation, and had only one-half ounce of clear residual urine.

Comment: This was also a successful case, as on his last visit he had only one-half ounce of residual urine, which was one-twelfth less than the amount found at the first examination. The character of the urine had also changed, and it was then clear, whereas before the operation it had been cloudy. The frequency had also diminished. This patient has not been heard from since his return, which leads me to think that he is much improved, as he was instructed to write if any unfavorable symptoms occurred.

His record after the operation was:

| Date. | Temp. A.M. | Temp. P.M. | Pulse. | Respiration | Urine. Ounces. | Stools. | |
|---|---|---|---|---|---|---|---|
| | Degrees. | | | | | | Operation 4 P.M. under eucaine. |
| 1st day. | 98.0 | 98.4 | 76 | 20 | 22 | 1 | Slept well all night. |
| 2d day. | 99.4 | 98.6 | 66 | 20 | 21 | 2 | Gave calomel, gr. ii. Slept well. |
| 3d day. | 98.0 | 98.4 | 72 | 28 | 32 | 0 | Slept well. |
| 4th day. | 98.0 | 98.0 | 78 | 20 | 47 | 1 | Slept fairly well. |
| 5th day. | 97.6 | 98.2 | 64 | 18 | 57 | 1 | |
| 6th day. | 97.0 | 98.0 | 60 | 28 | 32 | 2 | Epsom salts every half hour for eight doses. Slept well. |
| 7th day. | 97.6 | 98.2 | 68 | 20 | 61 | 4 | Slept well. |

Case VIII.—Cooper, aged sixty years. Strong, well-nourished man, about medium height.

History: The patient had been well up to sixteen months ago, when he began to pass urine with increased frequency, which troubled him, especially at night. At present he urinates six or seven times during the day and five or six times during the night. He does not experience much pain.

Examination: Palpation of kidneys, negative; no suprapubic tenderness or dulness. External genitals normal; rectal examination shows the seminal vesicles to be normal; prostate increased in size about one-half or three-quarters. Urethral examination shows the canal to be of a calibre of 26 French for six inches, when there is an impediment. A No. 18 French coudé soft-rubber catheter passes this and draws off two ounces of residual urine. A straight catheter of the same size would not pass the prostatic urethra. Catheterization causes some hemorrhage. The impediment in this case does not seem to be so great by urethra as the prostate indicates by rectal touch, which leads me to think that it must be an enlargement of the lateral lobes.

Urine analysis (Dr. Brooks): Pale reddish-yellow, acid, faintly cloudy; sediment nebulous, faint; specific gravity, 1.014; urea, 1.6 per cent.; total solids, 3.22 per cent.; albumin, distinct trace with Heller's test, heavy trace with Esbach's. Microscopically—innumerable pus cells, often in irregular masses of twenty to forty cells; occasional blood corpuscles; numerous atypical vesical epithelia; occasional small hyaline, finely granular, and epithelial casts.

Operation: On account of the spasmodic condition of his deep and posterior urethra, it took considerable time to wash out his bladder and cocainize it and the urethra. It also required six minutes to pass the instrument into the bladder after his hips had been elevated by a sandbag. Three incisions were made: (1) Posterior, 3½ cm. long; time two minutes; current 42 amperes. (2) Right lateral, 3¼ cm. long; time one and three-quarters minutes; current 45 amperes. (3) Left lateral, 3¼ cm. long; time one and three-quarters minutes; current 45 amperes.

At the end of the first cut the carbon burned out, and there was a delay of about five minutes until a new attachment was made, so that the patient must have been nearly from under the influence when the last two cuts were made. He was perfectly quiet, however, throughout the entire operation, although he said afterward that it had hurt him considerably He was able to walk about immediately after the operation.

From this date his temperature and pulse were normal. He passed sloughs for ten to twenty days.

Comment: This was an extremely interesting case on account of the spasmodic condition of the urethra, the burning out of the carbon, the elevation of temper-

ature, and the small amount of urine passed after the operation.

| 7th day. | 98.. | 99.0 | 70.0 | 74.0 | 17 | 54 | 2 | Patient is now passing urine very freely in large quantities. |

The spasmodic condition in this case was marked, although I do not know if it was any more so than in some of the others. At any rate, it made more of an impression upon me, as I had for some time been considering the question as to whether or not this operation should be performed under general anæsthesia. The burning out of the carbon also caused some delay, as it required some minutes to adjust another, and I think that perhaps it would have been better for the patient if I had desisted at this point, which was after the posterior incision, and continued the operation at some other time. Such a postponement would certainly have saved the patient several minutes of pain. This was the first case in which I had used the electric current by means of a transformer instead of the portable battery, and the burning out of the carbon led me to think that perhaps in the future it would be better to use the battery in preference. I decided, however, not to abandon it without another trial. The elevation of temperature, in this case 104.4° F., was greater than that in any other on which I had previously operated, and I was quite alarmed about the patient during the first forty-eight hours. Just what the cause of this was I do not know, as the patient was in better condition before the operation than others upon whom I have operated. This case again showed me the value of a diuretic when the kidneys are not excreting sufficient urine. Since the operation I have not had an opportunity of examining his urine, and do not know the amount of residual urine present in his bladder. He has, however, told me that he urinates only three times a day and once at night. He attributes his arising to pass urine to the fact that he takes tea with his evening meal and sleeps between nine and ten hours a night.

Case IX.—Journalist, aged sixty-one years. A thin but well-nourished man, above medium height, looking somewhat older than the age given.

History: He had noticed for some years that his frequency of urination was increasing, although it had not begun to trouble him until ten months ago, when he found that the desire to pass water was rapidly becoming more frequent and imperative, so that it was annoying during the day and at night interfered with his rest. At times during the day he could not hold it, and at night it often escaped during his sleep, notwithstanding the fact that he was in the habit of arising many times to pass urine. He estimated that he generally urinated every hour or hour and a half during the day and every half-hour during the night. The act of micturition was preceded and accompanied by a great deal of pain. He stated that he had never had an attack of retention. He had had in his younger days four or five attacks of urethritis, each lasting from several weeks to a year.

Examination: External palpation of kidneys, negative; percussion and palpation of the bladder negative. External genitals normal. Rectal examination shows the prostate to be increased about one-third in size, the left lobe being the larger. Seminal vesicles negative. Urethral examination—calibre of canal, 26 French down to the deep urethra, where considerable narrowing is noticed. There are two points of obstruction, one at six inches, the other at seven. The residual urine drawn off by a No. 12 catheter amounts to nine ounces.

Urinary report (Dr. Brooks): Yellow, fetid odor; ammoniacal, ropy in consistence; sediment, yellowish-green, mucoid, abundant; transparency, very cloudy; specific gravity, 1.024; urea, 1.6 per cent.; total solids, 3.22 per cent.; albumin, heavy trace with Heller's test; strong with Esbach's. Microscopically—innumerable pus embedded in mucus; numerous red blood corpuscles; occasional flakes of vesical epithelia; small number from deeper layers and from prostatic region; numerous large triple phosphate crystals.

Operation: The washing out of the bladder in this case was very tedious, requiring about three-quarters of an hour, on account of the small size of the catheter and the amount of solution which had to be injected before the washings were clear. After the bladder was clean, one-half ounce of eucaine solution was injected into the prostatic urethra and vesical neck and then along the urethra, while the catheter was being withdrawn. It was then almost impossible, on account of the spasm, to push the catheter back again, in order to inject the necessary six ounces of fluid into the bladder prior to the operation, notwithstanding the fact that the mucous membrane of the bladder and entire urethra was under the anæsthetic effect of the eucaine. This was finally accomplished, however, and more eucaine was injected before the water, and the catheter was then quickly withdrawn with the purpose of immediately inserting the instrument and operating before the combined action of the eucaine injections had passed away. A sandbag was placed beneath the hips, and after ten minutes of patient manipulation the instrument was finally introduced into the bladder. The beak of the instrument was then turned downward and pulled up against the base of the prostate. The introduction of the finger into the rectum was attended with great difficulty on account of the spasm of the adductor muscles of the thigh. Three cuts were made, a posterior and two lateral, and were accompanied by a great deal of pain: (1) Posterior, 3½ cm. long; time three minutes; current 45 amperes. (2) Left lateral, 3 cm. long; time two and one-half minutes; current 45 amperes. (3) Right lateral, 3 cm. long; time two and one-half minutes; current 45 amperes. The patient was in fair condition after the operation, although he had suffered considerably.

The patient passed the last slough on the seventeenth day. At present, two months later, he has no pain at all. Sometimes he can pass the entire night without urinating, although he has usually to get up once or twice. He urinates two or three times during the day. There is no burning. Residual urine, three and one-half ounces. The patient has been much improved by the operation, as can be judged from the absence of pain and the diminished frequency and also the diminution in residual urine. The operation has cured the patient of two of his most annoying symptoms, dribbling during the day and incontinence at night.

Comment: This last case has firmly convinced me

that, notwithstanding the statements of others, many of these operations are attended with pain and spasmodic contractions of the vesical and urethral sphincters, and that in every case in which there is a delay in the preparation for the operation after the introduction of the eucaine, or in which muscular spasms are present, a general anæsthetic should be given.

Case X.—Engraver, aged fifty-nine years. Man of medium height, bald, gray, having the appearance of a man prematurely old.

History: Family history negative. The patient had two or three slight attacks of neuritis when a young man. He has been troubled for some months with frequency of urination at night. During the day he passes urine five to six times, and during the night four or five times. Pain is not marked. He complains principally of frequency.

Examination: Palpation of the kidneys is negative; there is no suprapubic tenderness on palpation or dulness on percussion. His external genitals are normal. Rectal examination shows the prostate to be only slightly enlarged and flattened, and an enlargement of the seminal vesicles on the left side.

Urinary report (Dr. Brooks): Pale yellow; ammoniacal odor; slightly cloudy; sediment white, moderate; alkaline; residual urine, two ounces; specific gravity, 1.008; albumin, by Heller's test, negative; faint trace with Esbach's; no sugar. Microscopically—occasional leucocyte; no blood; innumerable triple phosphate crystals; no casts. Examination of urethra: Meatus small; after cutting admitted a catheter, 26 French, as far as six inches, when an impediment was found, by which only a 12 French soft-rubber coudé could be passed without an anæsthetic. Residual urine, one and one-half ounces.

Operation: The bladder was washed out with boric-acid solution and injected with four-per-cent. eucaine solution, as was also the urethra. An attempt was then made to pass the incisor, but after ten minutes of manipulation it was found impossible to introduce it into the bladder. As it appeared to me that this was due to a spasmodic condition, the patient was put under nitrous-oxide anæsthesia. The instrument was then inserted without difficulty.

Three incisions were made through the gland: (1) Posterior, 3 cm. long; time eighty seconds; current 45 amperes. (2) Anterior, 2 cm. long; time fifty seconds; current 45 amperes. (3) Left side, 2½ cm. long; time seventy seconds; current 45 amperes. The electric current, in this instance, was also obtained by means of a transformer attached to the electric light of the chandelier by which the hospital was illuminated. The operation, from the time that the anæsthetic was administered to its completion, was but five minutes, almost immediately after which the patient got up and walked away. The bladder was washed out with boric-acid solution before the anæsthetic was administered, and six ounces were left in his bladder.

| 4th day. | 98.0 | 99.2 | 70 | 80 | 17 | 43 | 1 | Appetite good. Slept well. |
| 5th day. | 98.0 | 99.0 | 74 | 70 | 18 | 52 | 1 | Put on regular diet. |
| 6th day. | 98.3 | 99.0 | 68 | 72 | 17 | 53 | 2 | Uneventful. |
| 7th day. | 98.0 | 99.4 | 72 | 70 | 18 | 45 | 1 | Uneventful. |

The patient was kept in bed for four days after this, eleven days in all, during which time his diet was general, and he was instructed to drink plenty of water, no tea or coffee, and his salol was kept up. After this, all treatment was discontinued. He now urinates four times during the night; no burning during micturition. Residual urine, a few drops.

Comment: This patient has improved greatly. He had a comparatively small amount of residual urine before the operation and his bladder possessed good tone. He was at a point, however, where he would probably have become rapidly worse had it not been for the operation. The striking feature of this case, in looking at the man, is the change in his personal appearance. Before the operation he looked like a man who was prematurely old and infirm; now he appears younger, stronger, and full of vigor. His eyes are brighter and clearer. Laughing-gas, in his case, proved a most successful means of producing general anæsthesia. The patient was quickly anæsthetized and came out almost immediately. A comparison of the ease with which this case was handled under general anæsthesia and the difficulty encountered with cases in the past under local anæsthesia has wedded me to the idea that this operation should be performed under the influence of a general anæsthetic, laughing-gas preferred.

Case XI.—Hatter, aged seventy-nine years. A well-preserved man, compactly built, having a large trunk and short but well-rounded extremities.

History: Past history negative. The patient states that he has always been a very healthy man. He has never had any venereal disease. He has been suffering from frequency of urination and pain and heaviness in the perineal region for some years, these symptoms varying at different times. At present he feels quite comfortable and is passing urine two or three times during the day and the same number of times at night, although occasionally when he has so-called "attacks" he passes it much more frequently.

Examination: Palpation of kidneys, negative; suprapubic palpation and percussion, negative.

Examination of external genitals shows the epididymis and testis on the right side to be quite enlarged, although not typical of any particular pathological condition; on the left side the gland was normal. Per rectum—the prostate was found to be about three times the normal size, well-rounded, and bulging into the rectum as a globular mass about the size of a small orange. Personally, I was able to slide the end of my finger up to the base of the gland, although none of the other surgeons present could succeed in accomplishing it. This was one of the so-called glandular hypertrophies and one favorable for enucleation. On urethral examination, the anterior part of the canal was of good calibre, but the posterior portion was tight, and a No. 10 French soft-rubber catheter passed with difficulty, causing some bleeding. Two ounces of residual urine were found to be present. It was evidently a case in which the hypertrophy of the lateral lobes was predominating. Enucleation, however, was out of the

question, as the patient would consent only to the electrical process, "the Bottini."

Examination of the urine showed: Color, reddish-yellow; slightly cloudy with a faint nebulous sediment; acid; specific gravity, 1.016; urea, 1.8 per cent.; total solids, 3.68 per cent.; albumin, Heller's test negative, Esbach's faint trace. The microscope showed numerous fine hyaline and granular casts, occasionally epitheliated; occasional leucocyte; rarely a red blood corpuscle; a small number of vesical epithelium from the superficial layers; urates, a trace.

Operation: The patient's bladder was washed out clean with boric acid, and six ounces of the solution were allowed to remain. The electrolyzer was then inserted, but stopped at the prostatic urethra. As this was thought to be due to a spasm, the patient was anæsthetized by means of nitrous-oxide gas, after which the incisor slipped quite easily into his bladder. Three cuts were then made: (1) Posterior, 4 cm. long; time, two minutes; current 45 amperes. (2) Right lateral, 4 cm. long; time two minutes; current 45 amperes. (3) Left lateral, 4 cm. long; time two minutes; current 45 amperes. These were the longest incisions that could be made by means of the incisor.

| 7th day | 98.4 | 99.3 | 70 | 74 | 17 | 49 | | |

The patient has been in good condition for several days; temperature and pulse normal. He has been passing the normal amount of urine. His appetite is good and bowels are regular. The patient was allowed to be up and about. He passed sloughs from the twelfth to the fourteenth day. Two months later the patient stated that he had no pain at all; that he urinated but twice at night. Examination by the rectum shows the patient's prostate to have diminished one-half in size and to be very hard. Examination of the urethra shows that an 18 French soft-rubber catheter can be easily passed into the bladder, the obstruction having greatly diminished, and only one ounce of residual urine being present.

Comment: This case has been one of unusual interest, as it was one of the large orange-like hypertrophies that are considered the most suitable for enucleation, and if I had had the consent of the patient I should have preferred to enucleate.

Case XII.—Clerk, aged sixty-four years. The patient is a man a little above medium height, strong, compact, and well preserved physically.

History: Family history negative. Past history of urethritis of short duration, when a young man; no complications. His present trouble has come on gradually, beginning about a year ago with frequency of urination, which has steadily increased, although for some time before this he has had local trouble once in a while. Now he has to get up at night four or five times to urinate, although during the day he passes urine normally. He has considerable urinary hesitancy, having to wait always a little before his urine begins to flow. There is a feeling of fulness over his pubes and a sense of heaviness in his perineum. He has never had an attack of retention, nor has he ever passed blood in his urine.

Examination: External—palpation of kidneys, negative. No dulness on percussion over the pubes; right testicle enlarged and soft, although there does not seem to be any characteristic pathological process going on; left testicle normal. Per rectum—the prostate seems to be increased one-half in size; left lobe larger than the right. Seminal vesicles and bladder, negative. Anterior urethra of good calibre, although a No. 14 French coudé catheter had to be used to enter the bladder, where two ounces of residual urine were found to be present.

Urinary examination, by Dr. Brooks, as follows: Color, pale yellow; odor, aromatic; clear with a nebulous sediment; reaction, acid; specific gravity, 1.020; albumin, minute trace by Heller's test, distinct by Esbach's; urea, 2.3 per cent.; total solids, 4.6 per cent. Microscopically—occasional hyaline and finely granular cast, rarely an epithelial; occasional single leucocyte; no blood corpuscles; occasional uric-acid crystals.

Operation: The bladder was washed out with difficulty and then cocainized, and the regular six ounces of solution injected into the bladder. The patient's hips were elevated by placing a sandbag under them, and an attempt was made to pass the instrument into the bladder. The contractions of the bladder sphincter were so strong that after ten minutes' trial it was considered desirable to perform the operation under general anæsthesia. Accordingly the patient was given the laughing-gas and was almost instantly under its influence. The instrument, which I had had so much difficulty with under local anæsthesia, now passed without difficulty through the urethra as far as the prostate, when, the handle having been pressed down, a little upward push sent it easily into the bladder.

Three cuts were made: (1) Posterior, 3½ cm. long; time one and one-half minutes; current 45 amperes. (2) Anterior, 2½ cm. long; time one minute; current 45 amperes. (3) Left lateral, 3 cm. long; time one and one-fourth minutes; current 45 amperes.

The patient came from under the influence of the anæsthesia after receiving a little pat on the cheek, and quickly got down off the table as if nothing had happened, and was able to pass a little fluid from his bladder.

|---|---|---|---|---|---|---|---|---|
| | A.M. | P.M. | A.M. | P.M. | | | | |
| | Degrees. | | | | | | | |
| 1st day. | .. | 99.0 | .. | 90 | .. | .. | .. | The operation was performed at 4 P.M. The electricity was taken from the street current by means of a transformer. The patient passed a good night after a hypodermic of morphine, passing twelve ounces of urine before going to sleep. Patient was given salol, gr. x. t.i.d., and instructed to drink freely. Diet, milk and Vichy. |
| 2d day. | 100 | 101.0 | 104 | 100 | 25 | 56 | 2 | Patient passed fifty-six ounces of urine during the day and night, and his bowels moved twice after taking a saline. |
| 3d day. | 101 | 100.0 | 100 | 94 | 24 | 46 | 0 | Patient has no pain. Feels comfortable. |
| 4th day. | 100 | 100.4 | 88 | 84 | 21 | 59 | 0 | Urine cloudy but not bloody. Appetite good. Takes water every hour to flush his kidneys. |
| 5th day. | 100 | 100.4 | 86 | 84 | 20 | 45 | 1 | Ordered Rochelle salts every hour until bowels move. Results good. |
| 6th day. | 98 | 99.4 | 74 | 70 | 18 | 51 | 2 | Patient put on regular diet. |
| 7th day. | 99 | 99.3 | 70 | 70 | 18 | 50 | 1 | Patient feels perfectly well. |

From this date the patient's recovery was uneventful. He passed sloughs from the eighth to the eighteenth day. I have seen this patient once since the operation, but did not have an opportunity of examin-

ing his bladder. He stated, however, that he felt much improved, that the feeling of heaviness and pain had disappeared, and that at present he never passed his urine more than twice during the night. He expressed himself as extremely pleased with the result.

In closing the discussion, I will say that the cases calling for operation are those in which the following conditions occur: Frequency of urination associated with the presence of residual urine; an increasing amount of residual urine; a troublesome cystitis due to obstruction; retention associated with catheter life; when tenesmus and irritability are so great that catheterization and vesical irrigations do not relieve; when catheterization is followed by bleeding and bad cystitis. It is my opinion that cases of hypertrophy should be operated on as soon as symptoms of bladder strain begin, as shown by frequency of urination and the presence of residual urine, and that we should not wait until a troublesome cystitis or marked retention develops. Symptoms of bladder strain are usually shown when from one to two ounces of residual urine are present.

Contraindications: When the patient's kidneys are in bad condition, an operation should not looked upon favorably, and if undertaken the patient and his relatives should be informed of the dangers to be encountered. In such cases it is advisable first to try by palliative methods to put the kidneys and bladder of the patient in the best possible condition by the administration of diluents, internal urinary antiseptics, and bladder irrigations. Care should be especially exercised in these cases not to empty too quickly the bladder of its urine, if much is present, as uræmia may then set in and place the patient in a position from which it would be impossible to rescue him. Cases of this kind are far more common than the general practitioner imagines.

The question of the diagnosis between stone and enlarged prostate is an interesting one. The symptoms of these two troubles are different when they occur separately, but if they were to occur together some confusion might be caused. Naturally, it would not be wise to do a Bottini operation on a case of vesical calculus when no hypertrophy was present; but I do not think that it would do any harm to operate on a case of hypertrophy of the prostate because a calculus happened to be in the bladder, as the cutting down of the prostatic impediment would enable the operator better to enter a lithotrite and evacuate the fragments, and if suprapubic lithotomy were performed the wound would be better able to heal if the prostatic impediment was a minimum one.

I do not follow the rule that a cystoscopic examination should immediately precede prostatic operations, as I consider the cystoscopy in these cases just as painful as the operation by the incisor, and also find that the cystoscope is at times more difficult to introduce. I can attribute a death of one of my former patients directly to cystoscopy performed before a proposed enucleation. The patient's kidneys were involved, and the cystoscopic examination brought on an attack of uræmia. The autopsy in this case showed the presence of pyelonephritis. I think that in almost all these cases a Thompson searcher can detect the presence of a calculus. In fact, I do not remember failing to detect a calculus in more than one case with a searcher in which I discovered it later with a cystoscope. If the cystoscope is to be used, this should be done at the time of the examination and not just before the operation.

An important question is the use of local or general anæsthesia in these cases. The majority of patients operated upon by me under local anæsthesia have complained of a great deal of pain at the time of the operation, and I know of other cases in which it has taken four or five men to hold a patient upon the table. It, therefore, seems to me that it is better to give a general anæsthetic, and of these I prefer nitrous-oxide gas, as scarcely any time is required for its administration, and the patient comes from under its influence almost immediately. It is also not dangerous and has no appreciable action upon the conditions of the kidneys. Of the two remaining, chloroform and ether, the first I consider dangerous, and the second affects the kidneys. Again, eucaine and cocaine are both considered dangerous because they produce syncope, although personally I have never had any bad effect from either of them. The amount of gas in a small cylinder of nitrous dioxide is about sufficient for three operations, and corresponds almost exactly to the amount of electricity in the storage battery used for this operation. One has often to choose between operating with the portable battery or by means of the current used for illuminating purposes. If one is operating in a private house, the battery is generally used, but in a hospital it is much more convenient to take the electricity from the fixture by means of a transformer. In the twelve cases here reported I have used the battery seven times and the so-called street current five times. The battery has failed me once, and the street current also once. It was much easier, however, to substitute another carbon in the second case than it would have been to procure another battery. The patient's heart should also be taken into consideration, as one with a weak action, due either to valvular trouble or fatty changes, does not bear an anæsthetic well, and also is not so well able to stand the shock of an operation.

Stricture of the urethra is another condition which would interfere with an operation. It is rather a rare occurrence to find a small stricture in an old prostatic, as generally it would have caused the patient trouble before he reached the prostatic age. If one is present, however, it should be dilated or cut by the regular methods some time before a Bottini operation is performed, so that when we come to use the incisor it can be easily inserted. In one of the cases upon which I contemplated a Bottini I found that the instrument caught in the deep urethra and postponed the operation until the attending physician could enlarge the stricture sufficiently to allow the incisor to be introduced.

In two other cases at the time of the opreation I found that the meatus was too small to admit the instrument, and on both these occasions it was cut immediately before inserting the incisor. In one case this caused considerable delay, and in both there was a great deal of bleeding connected with the operation. In still two other cases I had to abandon the operation on account of inability to introduce the incisor through the cut-off muscle, notwithstanding the fact that the pelvis was elevated and the parts were thoroughly anæsthetized. In two others upon whom I operated, and could not pass the incisor under a local anæsthetic, I had no difficulty in doing so under general anæsthesia. In another case I could insert the instrument through the compressor urethræ muscle into the posterior urethra, but then could not pass the bladder sphincter. On account of unwillingness on the part of this patient to take a general anæsthetic I was obliged to abandon the operation.

In regard to the preparation of a patient for the operation it is simply necessary to have him under the influence of some urinary antiseptic such as salol, urotropin, or one of the benzoates. I usually give ten grains of salol three times a day before and after the operation, unless the urine is ammoniacal, in which case I prescribe the same amount of urotropin. The patient's bowels should be washed out before the opera-

tion, and it is better to give only a fluid meal, although with a local anæsthetic or laughing-gas the operation can usually be done on a full stomach without causing the patient to vomit.

The important parts of the preparation are the solutions, and the arrangement of the cooling apparatus, battery, etc., as well as seeing that all the instruments necessary are at hand. The instruments and apparatus required are a soft-rubber elbow catheter; a large rubber hand syringe and a small urethral one; a scalpel; a Bottini incisor; a fountain syringe, and two pieces of tubing, one leading from the douche bag to the instrument, the other from the instrument to the receptacle on the floor; a galvano-cautery battery, or a transformer with a portable amperemeter; glycerin, solution of eucaine (four per cent.), saturated solution of boric acid, and a cylinder of laughing-gas.

Steps of the operation: "Place the patient on his back on the table, the bowels having been washed out. Hang the fountain syringe on the wall to the patient's left, connected with the incisor. Place the battery on the stool on the left of the patient and within reach of the operator. Pass a catheter lubricated with glycerin into the bladder and wash it out by means of a large rubber syringe until clean. Inject a eucaine solution (four per cent.) into the neck of the bladder and urethra by means of a urethral syringe through the catheter as it is being slowly withdrawn. Inject six ounces of boric-acid solution into the bladder and allow it to remain. Pass the incisor into the bladder. If it will not enter readily, put a pillow under the hips. If then the incisor cannot be made to enter, give an anæsthetic (laughing-gas preferably). Connect the incisor in the bladder by means of the cable with the battery. Turn the incisor so that its beak will point downward. Insert the left forefinger into the rectum and hook it over the base of the prostate. Pull the incisor forward until its tip is felt on or near the finger in the rectum. Withdraw the finger and take hold of the handle of the instrument with the same hand. See that the contact screw is turned tight and that the water is running through the cooling apparatus. Throw in the two cells and turn on the current to forty or forty-five amperes. Turn the wheel until the knife has gone forward and backward through the floor of the prostate. Turn the instrument at a right angle and cut through the larger lateral lobe, and then turn it again at a right angle and cut through the upper or anterior part. Return the patient to bed. If the operation is followed by retention, pass a catheter and allow it to remain for one or two days. After-treatment: Urinary antiseptics, diluents, and antispasmodics."

One writer recommends that an assistant should hold his finger in the rectum while the operation is being performed. This I mention simply to condemn it, as in order to feel the tip of the instrument some upward pressure has to be made, which might push up the anterior wall of the rectum sufficiently to allow the cautery knife to cut through and make a recto-vesical or urethral fistula.

Frequent questions that are asked regarding the operation are: Which cuts are best to make? What length should they be? What amount of electricity should be used? What time should be taken for each cut? These are all very interesting and were the ones that puzzled me the most in the beginning.

In regard to the first question, I find that in eleven of the cases I made three cuts. In seven of these the incisions were a posterior and two laterals, while in four others the incisions were posterior, anterior, and one lateral. I looked forward with a great deal of interest to the result of these two respective groups of cuts at the same time, feeling that the cases with the two lateral incisions would prove the best. The results have shown me, however, that as far as these cases are concerned I was wrong, and that the ones with the anterior and posterior cuts were the best. The length of these incisions varies according to the size of the prostate; the prostate is one and one-quarter inches long, which is about 3.2 cm. It would therefore seem that these incisions should be at least 3 cm. in length. The largest incision that can be made by the incisor is 4 cm., which is a little over one and one-half inches, and we would naturally think that a hypertrophied gland would have at least one-quarter of an inch enlargement, and would consequently require the maximum incision. There is generally, however, too much timidity on the part of the surgeon, and he is afraid of cutting too far, and perhaps even of going out of the posterior urethra. This is possible but not probable, and from the comparative tables given above it would seem impossible for such an occurrence to take place when sufficient hypertrophy was present to cause an impediment to the flow of urine.

I should therefore say that in moderate cases the posterior incision should be 3.5 cm. in length, and that in all marked cases it should be 4 cm. I am in the habit at present of making the lateral cuts 0.5 cm. less than the posterior one, and the anterior one 1 cm. less. I feel, however, that I am leaning too much on the side of conservatism, as I am always making the anterior cut shorter than the long diameter of the normal gland.

The strength of the electric current should be from forty to fifty amperes. Personally I use forty-five amperes in nearly every case. Concerning the time to be taken for each cut, it must be said that the time spent on the incision should depend upon its length. I notice in looking over the cases in this report that it has taken me anywhere from one and one-quarter to three minutes to make an incision 3 cm. long. It seems to me that it is wrong to make the cuts too quickly, as sufficient time ought to be taken to cause the most complete destruction of tissue possible along the line of the incision, and although it is shown in these tables, taking three inches as a standard, that from two to two and one-half minutes have been spent on this cut, I think that it would be wiser to spend at least three minutes on the posterior cut, with from two to two and one-half minutes on the others.

One of the most important points in the technique of the operation is to have the end of the instrument, while making the posterior incision, well down behind the prostatic border, and after this is caught there the operator should be careful not to hold the instrument so that its shaft will point toward the table or even be parallel with it, but it should be rather inclined a little upward. The wisdom of this can be understood when it is remembered that in the posterior position the concavity of the instrument corresponds to the convexity of the gland—in other words, that one fits into the other; then we can see that by depressing the handle of the instrument its point will tend to ride up toward the summit of the posterior prostatic incline, and the cut may not be made deep enough through the base of the collar. This is especially liable to happen if there is a pillow or sandbag under the hips of the patient. Again, when the instrument is *in situ* the patient often tends to pull himself backward away from it, and if the handle is depressed the beak of the instrument is liable to ride over the prostate into the membranous urethra, in which an incision would do no good, and perhaps much harm. Care must also be taken in making the anterior incision, when the beak of the instrument is turned upward not to have the handle too high, as then the beak might slip from the base to the convexity of the collar, or if the patient were to draw backward it might slip out into the membranous urethra.

The Bottini operation produces its good effects in

two ways: first, by making a furrow through the gland, lowering the height of the dam, and thus allowing the bladder to empty itself, and secondly by cutting through the blood-vessels and searing them so that the blood supply to the gland is cut off, and thus atrophy is induced. It can be seen that a good result will not be immediate, but that first the sloughs caused by the burn will have to be thrown off, and secondly that the atrophy of the gland must take place. The sloughs are thrown off usually from the seventh to the twenty-first day, although this may take place even later. The largest slough that I have ever seen was thrown off on the twenty-seventh day. These sloughs, or threads, which are thrown off, according to Sondern's pathological report,[1] consist of hypertrophied tissue of the prostate gland, the increase being in the fibro-muscular structure. In regard to the appearance of the glandular tissue, this sometimes shows evidence of atrophy and at other times does not. There are evidences of fatty changes and some inflammatory exudate or infiltration near the eschar. In the reports given there were no indications of cystic degeneration having been present.

After the operation, for the first few days there is very little elevation of pulse or temperature. In some cases this does occur, and should be treated accordingly.

If possible a catheter should not be passed after the operation until the sloughs have been thrown off, as this tends to keep the parts irritated, and may induce hemorrhage and the formation of granulation tissue.

As in many of these cases there is a complete chronic retention, it is advisable to insert a catheter and keep it in for forty-eight hours after the operation, and then if necessary—and it generally is in such cases—to catheterize every six or eight hours until the sloughs have been thrown off. Keeping up catheterization will depend on the benefit derived from the removal of the prostatic impediment and also on the tone of the bladder wall. If no improvement shows itself after treatment, and if the patient is still unable to urinate, a second operation should be performed. If the patient has complete retention and nothing can be passed into his bladder, he should either be aspirated suprapubically or a perineal section be performed.

N. B.: A patient with complete retention should never be operated on until after he has been broken into the catheter habit.

It must not be imagined that on removing the obstruction in these cases the patient will be immediately relieved of all his symptoms, as the symptoms depend upon the cystitis and atony of the bladder that have been brought on by the obstruction; but naturally if the cause has been removed it is much easier to benefit his condition.

The most difficult symptom to cure is the burning feeling or tenesmus. This is probably due to congestion, and is a symptom of cystitis. It remains in some cases more than in others, in a number occurring especially at night, and has caused me often to wonder if perhaps the cautery knife had not in some cases gone through into the plexus of veins outside of the capsula propria, and in shutting them off had not also impeded the return flow of blood from the vesical veins, and thus kept up the passive congestion after the impediment has been removed.

As there may be some details in the after-treatment that I have not mentioned, I will again quote from my article in the *New York Medical Journal* of April 29th:

"Immediately after the operation the patient should be put in bed. He is generally able to walk from the table to his bed, although it is safer to carry him. The internal treatment consists in urinary antiseptics, diluents, and antispasmodics, if necessary. As a diluent water taken in large quantities is usually sufficient. If it is found, however, that the patient will not drink much, and that the amount of urine passed is below normal, its flow should be further stimulated by a mild diuretic, and for this purpose I am in the habit of giving a mixture of gr. xx. of acetate of potassium and ♏ xx. of sweet spirits of nitre, three times a day in a glass of water. As a urinary antiseptic I generally give salol in ten-grain doses, three times a day, or urotropin in the same strength, the latter preferably when the urine is foul and ammoniacal. Benzoate of sodium and benzoic acid in fifteen-grain doses are also of service. The antispasmodics are codeine, morphine, and belladonna. These are given for frequency, pain, tenesmus, or burning. They may be prescribed singly or combined, and afford the patient a great deal of relief. Codeine may be given alone, or in combination with belladonna, and perhaps benzoate of sodium. Morphine I rarely use, and then only for pain. It is very efficacious in combination with the extract of belladonna, a quarter of a grain each, in suppositories at night, in cases in which there is a great deal of frequency, pain, burning, and tenesmus. The diet should be liquid for the first few days, then semi-solid (soft), and full diet at the end of the week, if the patient has no rise of temperature and is feeling well.

"If there is much hemorrhage, it can usually be stopped by a hot irrigation, and if this does not succeed a perineal section should be performed, after which a thick-walled perineal tube can be inserted into the bladder, around which gauze can be packed, thus making pressure between the sides of the tube and the cut posterior urethra.

"The bowels should be moved by salines on the second day, after which they should be kept open for some days.

"An elevation of temperature usually takes place on the night of the operation or on the following day, rising to 100° to 105° F. This generally goes down to normal after the bowels have been moved, but I have seen patients with a temperature of from 99° to 102° F. for some weeks after the operation. In such a case the fever usually disappears after the sloughs have been thrown off.

"When the bladder and the kidneys are very much involved, a continuous high temperature may indicate a disease of the latter organ, which should then be treated accordingly Extravasation of urine and perineal abscess might occur, but it is improbable, as the tissues are practically seared and sealed by the burning process."

In conclusion I can only reiterate what I said in my last paper on the subject; that is, that of all the operative procedures so far devised for the treatment of prostatic hypertrophy this is the one which exposes the patient to the least danger and is attended by the best results. It is wonderful to see the change in some patients. An old man, nervous and irritable, with a dull, sordid look, will appear in a few weeks perfectly transformed. He will often seem quite sprightly, while the expression of his face has so changed that his eyes seem bright and shining, in this way exhibiting exactly the opposite picture from one who has been operated upon by castration.

It will be most interesting in the future to study the nervous development of these patients, and to see if they have any of the sequelæ that follow in those who have been operated upon by other methods.

63 West Fifty-fourth Street.

**Fetid Breath,** when due to chronic affections of the air passages, is best treated by intratracheal injections of carbonate of creosote, employing quantities of from 0.5 to 1.5 c.c. (gtt. xv. to xlv.).—Bayer.

# NEPHRO-URETERECTOMY FOR TRAUMATIC HÆMATO-HYDRO-NEPHRO-URETEROSIS.[1]

By JOHN H. SUMMERS, Jr., M.D.,

OMAHA, NEB.,

PROFESSOR OF SURGERY IN THE OMAHA MEDICAL COLLEGE; SURGEON TO THE CLARKSON MEMORIAL AND TO THE DOUGLAS COUNTY HOSPITALS.

Injuries of the kidney resulting from blows, kicks, and falls upon the abdomen and loin regions occur sufficiently often to be almost common. The damage done to the kidney by such violence varies from simple contusion to almost complete pulpification. It is not my purpose to discuss all of these varying lesions with their symptomatology, but rather to confine myself to a consideration of a case of the injury and its consequences, which necessitated the carrying out of the procedure which is the subject title of this communication.

Nora L——, unmarried, aged thirty-eight years, a native of Ireland, with a negative family history and previous good health, was first seen by the writer December 3, 1898. From Dr. H. B. Wilson, with whom she was visited in consultation, the following was gathered: On the evening of November 29, 1898, the woman slipped and fell so that her right side (ileo-costal space) struck against the edge of the sidewalk. She had been able to arise and reach her home, only a short distance away, unaided. Dr. Wilson saw the patient within an hour after the accident, and found her somewhat shocked and in considerable pain, this pain being complained of mostly in the right kidney region, in front and behind. A hypodermic injection of morphine was given. She was not seen again until the next morning, when it was learned that she had had a comfortable night and that considerable bloody urine had been passed in the early morning—none having been voided after the fall until that time. The passing of bloody urine continued; the temperature ranged from 1° to 2° F. above normal; the pulse began to increase in frequency, varying from 84 to 100 per minute. The patient took a fair amount of nourishment, but was contented to remain in bed, feeling too weak to rise. This was the state of affairs when I first saw the woman.

Examination of the right lumbar region disclosed a tumor which could be seen as well as felt. It was only slightly painful on palpation, and had a boggy feel as if made up of clotted blood contained in a not very tense enveloping membrane. The tumor did not bulge in the loin, but projected downward and slightly inward so as to be limited in front and below within vertical and horizontal lines joining one another at right angles at a point 5 cm. within and 2.5 cm. above the anterior superior iliac spine. It seemed a little broader than a man's hand, but its posterior border could not be made out.

It was advised that the woman should be kept under close observation, so that early surgical interference could be resorted to if septic infection supervened. The patient was not seen again until December 17, 1898, when she was brought to the Clarkson Hospital. Her general condition was not favorable. There had been loss of flesh, strength, and heart tone. The pulse was only 84, but weak; temperature, 98.8° F. Locally a remarkable change had taken place. A cystic growth occupied the lower median part of the abdomen, extending well over toward the left iliac spine and down into the pelvis; it also distended the right side of the abdomen, extending up into the kidney region. The tumor might have been mistaken for an ovarian cyst. A physician visiting the case on behalf (legal) of the city, imagined the woman pregnant, about seven months, and quizzed her regarding this possibility. It was learned that the passing of dark bloody urine had kept up. Microscopic examination proved that the coloring matter of the urine, which precipitated upon standing, was composed of broken-down blood elements. Upon using the Harris instrument it was observed that the fluid removed from the left bladder basin was normal urine; that from the right bladder basin was a bloody, watery fluid.

When I first saw the case it was my opinion that we had to deal with a retro-peritoneal collection of blood due to a rupture of the kidney. When the patient was next seen in the hospital this idea had to be abandoned, and a diagnosis of hydronephrosis of the right kidney, the result of an injury to its ureter, was thought most reasonable; yet we could not harmonize a free discharge of a bloody fluid from this ureter (more in volume than the normal urine from the left healthy ureter) with an obstruction in its lumen sufficiently great to bring about such an enormous hydronephrosis.

The ureters were not catheterized, as it was thought unwise to run the chance of making a false passage through a presumably partly torn and tortuous canal. An operation was planned to examine the condition of the kidney tissue itself as to structural changes, with the hope of saving the organ by repairing the ureter. On December 21, 1898, the following operation was carried out: Under chloroform narcosis and with the patient lying on the left side, an incision was made commencing at the inner edge of the erector-spinæ muscles and extending through the centre of the ileo-costal space, curving downward toward the pubic spine. This incision reached 5 cm. below the anterior superior iliac spine, and was 3.5 cm. to the inner side of this point. After exposing the upper outer part of the cystic, irregularly shaped tumor, it was found impossible to isolate the ureter. A trocar was introduced and the tumor reduced by the evacuation of many quarts, not measured, of a dark-colored watery fluid (the same as passed per urethram). Before proceeding further the tumor was so separated upon its outer side as to allow of an examination of the ureter, which was found much thickened and distended. Above near its origin it had a diameter of 2.5 cm., which tapered down gradually below to where the right common iliac artery was crossed, at which point it was 1.5 cm. in diameter. There was no obstruction or injury to the ureter. As the kidney and ureter were useless it was decided to remove both. In order to lessen the danger of injury to the renal artery and vein, as well as to facilitate necessary manipulations in the enucleation of the tumor sac, the vessels were now isolated, secured with chromic catgut, and divided at a sufficient distance away from the ligatures to remove any danger from hemorrhage resulting from a possible slipping of the ligatures. The lobulated sac was peeled out from the pelvis and right side of the abdomen. In doing this it was necessary to separate the sac wall from the outer and anterior surface of the ascending vena cava. This latter procedure was not easy, nor was it comfortable for the operator. Some trouble was experienced in separating the peritoneum from the anterior, inner surface of the tumor, because of the difficulty of lifting and keeping the contents of the peritoneal sac well out of the way toward the left side of the abdomen. After the collapsed tumor sac was delivered no difficulty was experienced in following the ureter down into the pelvis near the bladder. It was ligated and divided, the stump being deep down and some distance below the lower angle of the abdominal incision. It was not thought wise to prolong the operation by attempting to remove the stump through a vaginal incision, because of the feeble condition of the subject and the small size of her virgin vagina, neither did the nature of the ureteral lesion

[1] Read before the Southwestern Iowa Medical Association, Creston, Ia., February 16, 1899.

justify the added risk. The whole operation was entirely an extra-peritoneal procedure. The wound was closed after the usual fashion with a gauze drain introduced at each angle. Repair was prompt, but recovery was somewhat slow. However, the patient left the hospital February 4, 1899, a perfectly well woman, having gained much in weight and general appearance.

On examination of the specimen, it was found that all semblance of kidney tissue had disappeared; there was no trace of either pyramidal or cortical substance. On the inner surface opposite the mouth of the ureter was a rent which did not extend quite through the sac wall. A plastic exudate with very firm adhesions had been observed external to the sac opposite this rent, which was evidently the source of the hemorrhage. I have not consulted my file of journals, but from the books in my library I have been able to find only a single case (fatal) in which a somewhat similar condition followed a traumatism, excepting the fact that the ureter was dilated not throughout its length, but only the upper portion near the kidney.

Discussing the subject of distention of the cavity of the kidney with blood, Henry Morris, quoting Rayer, says: "Hæmaturia, more or less considerable, is the most constant result of contusions of the kidney; but it is excessively rare that blood after being coagulated in the ureter or pelvis of the kidney is accumulated more and more in such a manner as to distend the kidney and to transform it into a large sac, extending from the hypochondrium to the iliac fossa. Renal tumors of this dimension are ordinarily the consequence of pyelitis, of a hydronephrosis, or of a cancerous, tuberculous, cystic, or hydatid degeneration. One can recognize, or at least suspect, that the distention of the kidney is a sequence of an internal hemorrhage by the nature of the case and the rapidity of the development of the tumor. Undoubtedly it will be difficult to distinguish during life a tumor formed by an extravasation of blood around the kidney and outside the peritoneum, from a tumor caused by the dilatation of the kidney by the blood accumulated within its cavity. Yet in extra-renal hemorrhages the tumor generally appears soon after the accident, and is circumscribed like renal tumors. A tumor due to blood effused within the cavity of the renal pelvis is formed later, and more slowly, than an infiltration of blood into the subserous cellular tissue, as the kidney is distended with more difficulty than the peritoneum can be detached from its connections."

Rate of growth: Morris, in speaking of the fatal case reported by M. Danyan, in which complete obliteration of kidney tissue resulted from pressure, due to the damming back of urine and blood following a traumatism to the upper portion of the ureter, says that it is seldom that the clinical history and source of a case of hydronephrosis afford accurate data for forming an opinion as to the rate of growth or development of the intra-abdominal tumor. In that case two calendar months (the time intervening between date of injury and death) were given as the maximum time necessary for the destruction of the pyramidal and cortical substance of a kidney and the formation of a large tumor by intro-renal pressure. The mechanism was the same as that usually producing hydronephrosis.

In my case the condition was brought about in a much shorter time, from November 29th to December 21st, three weeks, and this may approximately be taken as the minimum time necessary to complete the atrophy and replacement of normal kidney structure by a large membranous sac. There is no reason to believe, either from the history of the patient or from an examination of the specimen, that any disease of the kidney antedated the injury; the same was true of Danyan's case. Hydronephrosis with or without dilatation of the ureter is commonly due to an obstruction to the outflow of the urine from the kidney. The obstruction may be situated in the urethra, bladder, or ureter. Now it is strange that a few cases have been reported in which no cause for the dilatation has been discoverable post mortem. Sutton, in speaking of this, says: "It is a curious fact that some of the largest hydronephroses, unilateral and bilateral, that have come under notice have been cases in which it was impossible to assign an adequate cause." I have not been able to satisfy my own mind as to the cause of the lesions in my own case; hemorrhage did it, but how I do not know—surely not by a clotting in the ureter, because there was always a patent ureter.

Howard Kelly has done three uretero-nephrectomies, one transperitoneal, the others extra-peritoneal, and to Kelly we are indebted for our knowledge of a beautiful technique. A French surgeon, Reynier, has also done the operation once. These operations were for tuberculous involvement of both kidney and ureter, the tumor in all cases being comparatively small. Whether or not a ureter should be removed with its kidney will depend upon circumstances. If the upper 5 to 7 cm. of the ureter are free from involvement of the disease for which the nephrectomy is indicated, then the ureter should be let alone; otherwise it had better be taken out in part or in whole. Heretofore, in tuberculosis of a kidney when I have removed the organ it has been my practice to cut off the ureter 5 to 10 cm. away from the kidney, and I believe I shall do the same hereafter unless the ureter is infiltrated with tuberculous material. In such a case it would appear better to remove the ureter, applying the same principles employed in operating for tuberculosis in other parts of the anatomy. As suggested by Kelly, the ureter may be removed at a second operation.

## A FRACTURE OF THE INFERIOR MAXILLA.

By HENRY L. O'BRIEN, D.D.S.,
BROOKLYN, N. Y.

In November, 1898, the writer was invited by Dr. H. B. Delatour, visiting surgeon to the Long Island College Hospital, to witness an operation for the removal of some necrosed bone from the inferior maxilla of a a patient of his in that hospital. The case was one of unusual interest to a dentist: the patient's jaw had been fractured some four months previous to the operation, and owing to the sloughing about the parts from necrosis, there had been but little union. He had received a number of other fractures of the superior and inferior maxillary bones, all of which had healed and bony union taken place, but the parts were left very much out of their natural positions, thereby causing a bad deformity as well as an ankylosed jaw. This unfortunate state of affairs was due to the accident happening away from civilization, and to the fact that what was done to restore the continuity of the fractures was necessarily with the crudest appliances; a piece of wire and bandages were the only things obtainable. As the fractures were only partially reduced there was left a deformity which not only destroyed the contour of the face, but greatly interfered with his speech and mastication. The manner in which the patient, Mr. H——, received his injuries was a peculiar one. Early in the spring of 1898, he with a party of other Brooklynites had gone to Alaska to prospect for gold, and while there he had been attacked by a silver-tip grizzly bear. The bear had knocked him down with a blow from his paw, laying open his scalp, and then had bitten his face until it was crushed almost out of human semblance, but fortunately not injuring his eyes. One of the miners who was a physician did

what he could to allay the sufferings of the young man. He found nine fractures of the superior and inferior maxillaries. The inferior maxillary was fractured in three places, at the angle on each side and

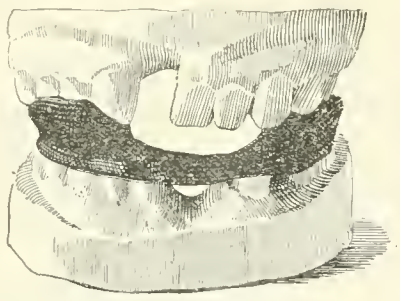

Fig. 1.—Interdental Splint.

again to the left of the symphysis. Here the bone was bitten completely through, and the patient claims the chin was twisted clear round to the right, and from the scars there is every indication of this being a fact. This portion of the bone the doctor forced back into place, and then bandaged the face and inserted a wire into the mouth to which a bandage was attached; this was at the line of the bicuspids and the corners of the mouth. Then by tightening the bandage at the top of the head the superior maxillaries were drawn up into place, or as far as they would go. The right and left upper molars and bicuspids had all but touched each other, and after being drawn up a large piece of bone was exfoliated from the roof of the mouth, carrying with it the right superior and lateral incisors. Pieces of dead bone subsequently came away from the inferior maxilla. The right portion of the inferior maxilla was dislocated at the articulation; this also had to be reduced almost daily for a time. There were indications of injury to the zygomatic process on both sides of the face, a fracture of the nose, large scalp wound, etc.

Dr. Delatour removed two fragments of dead bone to which were attached the left inferior lateral canine and first bicuspid teeth. These fragments largely consisted of process. There had also been a large piece of the body of the bone exfoliated through a fistulous opening under the jaw, while the patient was in Alaska; this piece of bone was in the form of a chip over an inch long and nearly as wide, leaving the opposing ends of the bone involved in the fracture like sharp points and in the worst possible condition for union. A chain saw was passed around each point of bone, and they were removed, leaving square ends and doing away with, perhaps, a little less than an inch of bone. The ends were sutured with silkworm gut passed through drill-holes, and were brought together without difficulty, but reducing the span of the lower arch.

At Dr. Delatour's suggestion I visited the hospital the next day to see if I could obtain an impression for

Fig. 2.—Splint Plate.

a splint to hold the fracture. I found the face very much swollen, due to the operation, and no possible chance of obtaining my impression. After waiting three days the swelling went down so that I could do something, although one could not get a lead pencil between the teeth at the cuspids. After a good deal of manœuvring I got an impression in sections, and made a short black rubber splint, which extended as far back as the bicuspids; but now the difficulty was to place it in the mouth. The wound had not been doing well up to this time. The muscles were straining at the left side of the inferior maxilla, and, in spite of the suture, had drawn that side of the bone inside the upper arch and toward the roof of the mouth. To remedy this it was decided to remove the suture, and, while the patient was under the anæsthetic, place the splint in position. Ether was given, the suture severed, a small quantity of necrosed bone was removed, and then after a good deal of manipulation the splint was adjusted.

The patient wore the splint over two months, and the wound caused by the operation healed completely. No bandages were necessary, and the splint could be easily removed by the patient for cleansing or while taking liquid food. There is quite firm union at the fracture, but the movements of the lower jaw are much restricted.

In the original dressing the fractures at the angles were held by a bandage drawn tightly over the head. This appears to have drawn the body of the bone upward and allowed the chin to drop downward. This feature, along with the contraction of the upper arch and drooping of the upper teeth, allowed very little play for speech or mastication.

I removed three of the upper molars that rested on the lower gums (the lower molars are absent excepting one) and had to use one of the old-fashioned "turnkeys" to do it, as it was impossible to get a pair of forceps between the jaws. I used a four-per-cent. solution of eucaine. With a hypodermic syringe, a few minims were injected at the side of each tooth, and the teeth were turned out quickly and without any pain to the patient, and to the great satisfaction of the operator, I then made and placed in the mouth the splint-plate seen in Fig. 2, and the patient is now equipped for masticating his food, although the movements of the inferior maxilla are very limited and the masticating surface is small; but we are in hopes that time will improve this condition. This plate rests on the gums and is also provided with gold crowns, one continuous one covering all the teeth to the right of the fracture, and the other covering the molar on the left; it also clasps the bicuspid. This steadies the fracture and yet allows of mastication, and if cleanliness is observed should last for a long time without injuring the teeth and giving every chance for a firm union of the parts. Upper and lower dentures can be made later on to give more masticating surface, but at present it is almost impossible to obtain an impression of the palatal surface. The superior maxillaries are not firm, there being considerable motion on pressure, due partially to the loss of the large piece of bone from the roof of the mouth and the fibrinous consolidation.

The patient was dismissed for the time being with the instructions to practise daily calisthenics with his jaw, to chew coarse food, and to make as much use of it as possible, even to the point of discomfort; and the chances are that in time he will attain almost the old freedom of movement, and it is to be expected a much firmer union will take place at the point of the fracture.

217 Ninth Street.

---

**Asphyxia.**—I do not consider traction on the tongue as being perfectly free from all danger; at least, I cannot imagine why muscle bundles should not be torn in the manipulations. By tickling the epiglottis nothing can be injured. We know by daily experience how anxiously we try to avoid touching the epiglottis in intralaryngeal operations, even after thorough cocainization. We are afraid of the reflex caused by the least sensation of tickling. Ought we not to learn by this experience? Therefore tickling the epiglottis might perhaps be tried as a means of resuscitation.—W. Freudenthal.

## A METHOD OF MAINTAINING APPROXIMATION AFTER COLLES' FRACTURE BY SHORT LATERAL SPLINTS WITHOUT PRESSURE ON THE TENDONS OR INTERFERENCE WITH THE CIRCULATION.

By A. E. ROCKEY, M.D.,

PORTLAND, ORE.

THREE years ago I had a bad result in the treatment of Colles' fracture in a woman past middle age. I should lack courage to make this confession if the example was unique, but I have seen others. The wrist was stiff, and it required much patience and perseverance with massage to restore it to a fair degree of usefulness. Great care had been taken with the case, and in looking for a cause I concluded that the fault lay in existing methods of treatment. The splint used was an anterior pistol-shaped one. The defect is that it makes pressure on the tendons and interferes with the circulation. The wonder is that bad results are not more frequent. Nothing more inimical to the function of the joint could be devised than anterior or posterior splints, and yet every text-book published gives them the first place in describing the treatment of this fracture.

The injury has already caused extravasation about the vessels and tendons. Then we are told to apply a splint which presses the tendons together in the wounded sheaths with a bandage which, if firm enough to maintain fixation, always interferes in greater or less degree with the circulation.

In discarding this colossal blunder of the past and examining the structures involved, I concluded that the only rational method of maintaining approximation was by lateral splints that would prevent pressure on the flexor and extensor tendons and not interfere with the circulation, and would permit movement of the joint during the healing process. The first plan was to use pieces of wood about three inches long, hollowed out to fit approximately the radial and ulnar sides of the wrist. The reduced fracture was to be held in position by an assistant. The splints were to be filled with soft plaster and pressed firmly into place at the sides of the wrist, not extending over the joint far enough to prevent free motion. Position was to be maintained by two adhesive strips. The splints were to be thick enough to raise the retaining adhesive strips above the skin, thus leaving important structures entirely free. I provided myself with some short pine blocks, a gouge, and some plaster.

The first patient was a Swiss laborer on a dairy farm. Reduction was effected under anæsthesia. Approximation was easily maintained by the splint described, and the result was perfect. There was very little pain or swelling, and in ten days these had entirely subsided and voluntary motion of the hand was easy and painless. The method was a success, but this was only the first step in the evolution of its adaptation to general practice

The next case was in a middle-aged woman, first seen at her residence in the evening. There was no plaster of Paris at hand, so I constructed what I then thought would be a temporary splint from the lid of a pasteboard shoe box. The lid was cut into strips one and three-quarters inches wide. Eight pieces two and three-quarters inches long were made, giving splints of four thicknesses each for the radial and ulnar sides of the wrist and of sufficient height at the edges to protect entirely the tendons and vessels on the palmar and dorsal surfaces from pressure. The fracture was carefully reduced and was then maintained in position by firm traction upon the hand and elbow by one of the family acting as assistant. The board was moistened with water, and a four-ply splint was pressed firmly on the radial and another on the ulnar side of the reduced fracture and held in position by two narrow strips of adhesive plaster, the palmar and dorsal surfaces of the wrist being entirely protected from pressure by the thickness of the splint. Over this a bandage was applied like that used in Moore's dressing.

The approximation was so well maintained by this simple device, materials for which are to be found everywhere, that it has been adopted as the best method for general use. A point to be observed is that the splints must be wide enough to curve around the sides of the wrist, but leaving sufficient space between at front and back to protect the flexor and extensor tendons entirely from pressure from the splints and thick enough to avoid pressure from the bandage. The adhesive strips may touch the skin lightly, but must make no pressure. The bandage may be applied with a moderate degree of firmness, but should be loosened somewhat on the second day after the splints have hardened to relieve the compression of the skin over the bony prominences at the sides of the wrist. In persons of delicate skin or thin tissues it will be well to watch the prominence of the styloid process of the ulna, and if after the second day there are signs of pressure irritation, a depression may be cut with a penknife or small gouge in the under side of the splint over this point. A sling wide enough to support the hand should be used for a week, but after the primary swelling subsides daily movement should be insisted upon, and the use of the hand may be begun at the end of the second week. The splints may be worn four weeks or more, as they do not interfere with motion and insure the safety of the union.

Perfect reduction of the fracture is of the first importance. General anæsthesia should be used as a rule. It is true that reduction may be made without it, but its more frequent adoption will lead to better results. An assistant should make firm traction upon the hand and counter-traction upon the forearm, and the operator should manipulate the fragments directly into position and then place the lateral splints and hold them by a circular clasp of the left hand while the first strip of adhesive plaster is applied around the carpal end of the splints. One more strip of plaster and the circular bandage complete the dressing. I have used this method in about twenty-five cases with great satisfaction, and have also described it to some of my colleagues in the profession, who have adopted it with success.

---

## COMPARATIVE CHEST MEASUREMENTS.

By H. M. LEE, M.D.,

ASSISTANT SURGEON THIRD REGIMENT, N. G. S. CONN.; LATELY SURGEON IN CHARGE SECOND BRIGADE HOSPITAL, FIRST DIVISION SECOND ARMY CORPS.

THE subject of chest measurements and the amount of chest expansion of the healthy man has been for some years a matter of interest, particularly to those surgeons who are required to examine applicants for the United States service and insurance organizations. The average chest expansion is set forth for the guidance of surgeons in these examinations, but it is often received with incredulity, and is moreover variable. These facts have led me to compile the average chest measurements from eight hundred men, examined by me for enlistment in the United States volunteer service.

The men were between the ages of eighteen and fifty years, the average age being twenty-six. The eight hundred taken for this table of measurements were all

healthy men, and were enlisted in the government service, or at least passed the board of surgeons. It may be well to note here that these men were from all walks of life, but the majority were accustomed to heavy exercise in their daily work, many being much in the open air, all well built and muscular.

Average measurement at complete expiration, 29.52327 ($29\frac{2}{5}$) inches; average measurement at complete inspiration, 33.28957 ($33\frac{1}{5}$) inches; average expansion, 3.76629 ($3\frac{4}{5}$) inches.

These figures (the average expansion) are somewhat surprising, being over one-half an inch greater than is generally taken as the average. My records show that age seems to play a small part as regards the expansion, for all the older men examined (the oldest being fifty years of age) had an average expansion of over three inches. The greatest variation was in the young (between eighteen and twenty-four years of age), the least and greatest expansion being found in these men. The smallest expansion recorded was two inches, the largest six inches, in the eight hundred men taken for this average.

## A CASE OF COMPLETE EXTERNAL DISLOCATION OF THE PATELLÆ.

By J. E. COURTNEY, M.D.,

FIRST ASSISTANT PHYSICIAN OF THE HUDSON RIVER STATE HOSPITAL, POUGHKEEPSIE, N. Y.

The case described and illustrated is interesting from its extreme rarity, its occurrence in early life, the failure of surgical measures to relieve the condition, the comparative comfort with which the subject was able

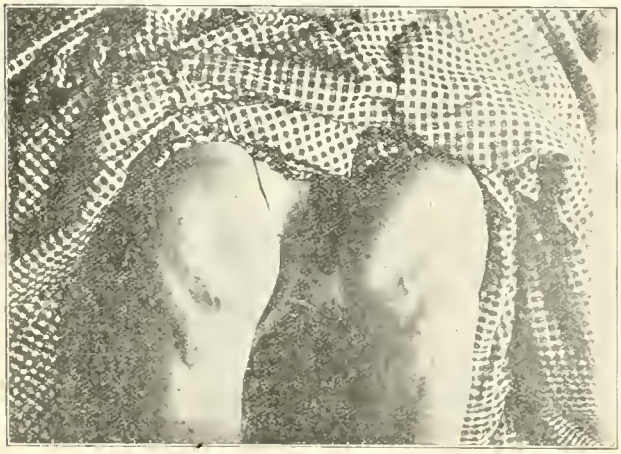

Fig. 1.

for years to lead an active life without artificial assistance, the peculiar changes in the joints, and the opportunity offered to study them after death.

When H. J——, a woman seventy-four years of age, came under my observation I was interested to find that in attempting to elicit the patella-tendon reflex the fingers went into depressions instead of striking

Fig. 2.

the tendons. The patellæ showed complete outward dislocation (Fig. 1). They rested on the outer condyles of the femurs, and with the legs fixed could be partially pushed back into their normal position, but immediately settled in the new position. The patient, her family, and physician all stated that the injury was received when she was fourteen years of age, and was the result of a fall while attempting to get into her carriage. The ligaments were stretched and their attachments so much strained that reduction could not be maintained. She was, however, soon able to move about, and during her life did not require a crutch or often a cane, and she was only stiff in rising or sitting, and a trifle shuffling in gait.

The patient died of senility. With the joints opened and the patellæ turned down (Fig. 2), it could be seen that the latter rested upon and had worn articular surfaces in the condyles, the one in the right knee infringing upon and slightly sharing the articular surface belonging to the tibia. The patellæ were at quite different angles to the shafts of the femurs. The right was almost vertical, and had simply moved outward. The ridge on its under surface had worn a groove in the articular surface, near the inner border; the outer border was well rounded, and there was a corresponding slight projection there of the external inner edge of the patella, thus making it more secure in its novel position than the left, which had worn quite a flat articular surface. The position of the left patella was quite different: the upper extremity had moved but little, while the lower was turned out at an angle of at least sixty degrees from the long axis of the femur; this caused the quadriceps tendon to play across the end of the femur, grooving it. The ridge on the inner surface of the left patella had entirely worn off; there was scarcely any articular cartilage on the new surfaces; the original articular surfaces of the femurs for the patellæ were filled in with small irregular exostoses.

## A CASE OF TETANUS TREATED WITH ANTITOXIN.

By A. de YOANNA, M.D.,

BROOKLYN, N. Y.,

LATE ATTENDING PHYSICIAN NERVOUS DISEASES DEPARTMENT, BELLEVUE HOSPITAL (O. D. P.).

La Monica Francesco, native of Italy, a healthy and strong longshoreman, on February 9th, in putting some barrels on a steamer, smashed his fourth finger so badly that he was compelled to go to the hospital for treatment. After five days in the hospital he was discharged as cured. On February 17th, during the day, he felt pain in the neck and spine, but he continued to work until evening. On going home, the pains kept on increasing, and during the night his jaw got locked in such a way that he was unable to drink anything.

The writer was called at 9 A.M. on February 18th and found the patient in the following condition: There were trismus and contractions of the facial muscles (facies tetanica). These contractions were getting worse with every convulsive attack; there was marked rigidity of the muscles of the neck, with spasm of the pharynx and larynx. Pulse, 120; temperature, 102° F.; respiration, 36, with oppression. The writer saw it was a case of tetanus. He looked at the finger at once, and while it seemed to be perfectly healed, there could be seen under one half of the nail something bluish. On being opened, a greenish pus exuded. After injection of cocaine the writer cut away one half of the nail and cleaned out all the dead tissues. For drainage gauze was used with a solution of one-half per cent. of iodine trichloride, the best disinfectant in such cases. The patient was immediately given bromide and chloral and sent to the board of health for tetanus antitoxin.

In the afternoon I injected 20 c.c. on the external part of the arm near the wounded finger, 20 c.c. on the right shoulder, and 20 c.c. all along the spine. These three doses of 20 c.c. each were injected during the course of six hours.

The next day, twelve hours after the last injection, I found the patient in very good condition. He could sit on the bed; the trismus was less; he could drink water and milk. I left orders to allow him as much of these as he wished. The pulse was 90; respiration regular; temperature normal. The injections were continued at the rate of 40 c.c. a day for three days. The patient improved rapidly, and three days after the first injection could go from one corner of the room to the other and get up and sit down quite well. The injections were continued for fifteen days, and 280 c.c. in all of antitoxin were given. The amount of antitoxin used was exceedingly great, and the results were very satisfactory, as the case shows.

It is right to note, also, to prove the gravity of the case and the good effects of the antitoxin used, that after the first three injections of 60 c.c. the pulse and respiration, which before were not proportional to the temperature (due to the involvement of the bulb in the morbid process), went down gradually and after twelve hours were normal. The patient on March 15th could walk very well, and the only thing left was a little stiffness, especially in the morning, of the muscles of back and legs. On April 15th he went to work as usual, in the best of health.

4 Third Place.

**Retained or Ectopic Testicle.**—The chief complications of a retained testicle or ectopic testicle are: Inflammation of the epididymis or testicle, gangrene, peritonitis (in abdominal cases), hernia, atrophy, hydrocele, hæmatocele, and sarcoma.—John Chalmers Da Costa.

## Progress of Medical Science.

**Non-Diphtheritic Pseudo-Rhinitis.**—Dr. J. Price-Brown, in a paper read before the Western Section of the American Laryngological, Rhinological, and Otological Association in March, 1899, drew the following conclusions: (1) Non-diphtheritic pseudo-membranous rhinitis does sometimes occur, and, though a very rare disease, it is probably as frequent as primary nasal catarrh. (2) On clinical grounds alone it is possible, in the majority of cases, to distinguish it from genuine diphtheritic disease. (3) Owing to a possible mistake in diagnosis, isolation in all cases should be imperative, until a reliable bacteriological examination might be made.

**For the Treatment of Acute Rheumatism** Favill (*Journal of the American Medical Association*, May 13, 1899, p. 1017) recommends that the bowels be emptied thoroughly, preferably with a mercurial, and that sodium salicylate be administered to its full analgesic effect, or, if it is not well borne by the stomach, oil of gaultheria. If salicylates are contraindicated by cerebral conditions, antipyrin, or some other suitable coal-tar analgesic, may be employed; and if these are contraindicated by circulatory or nervous complication, opium may be used for the relief of pain. As the pain is controlled by these means, perhaps together with heat and immobilization, salicylates should be withheld and the system saturated with alkali until the active process seems controlled. Iron should be given simultaneously or subsequently if the condition of the bowels and the liver permits. Throughout the attack intestinal hygiene should be promoted by means of a mercurial, cholagogue, or saline.

**Chemical Examination of Human Breast Milk.**—Dr. Adriance (*Archives of Pediatrics*, vol. xiv., No. 2) sums up a report upon the medical examination of two hundred specimens of human breast milk as follows: (1) Excessive fats or proteids may cause gastro-intestinal symptoms in the nursing infant. (2) Excessive fats may be reduced by diminishing the nitrogenous elements in the mother's diet. (3) Excessive proteids may be reduced by a proper amount of exercise. (4) Excessive proteids are especially apt to cause gastro-intestinal symptoms during the colostrum period. (5) The proteids being higher during the colostrum period of premature confinement, present dangers to the untimely born infant. (6) Deterioration in the human milk is marked by a reduction in the proteids and total solids, or in the proteids alone. (7) This deterioration takes place normally during the later months of lactation, and, unless proper attention is paid to the infant's diet, is accompanied by a loss of weight, or the child's gain is below the normal standard. (8) When this deterioration occurs earlier it may be the forerunner of the cessation of lactation, but well-directed treatment may improve the condition of the milk.

**The Ocular Phenomena in General Paresis.**—In the *British Medical Journal*, ii., 1898, September 10th, W. R. Dawson and D. F. Rambaut record a series of observation made on this disease in the Richmond Asylum, Dublin. Some forty cases are reported. In ninety-two per cent. of the cases the pupils were unequal, but the authors state that, since this condition is by no means unknown in healthy people, too much stress should not be put upon it. In twenty-three cases the size of the pupils was recorded; eight patients had mydriasis in both eyes, and six myosis; three had myosis in one eye alone. In one case myosis and mydriasis were found. Reflex iridoplegia was noted

five times; in two the eyes were mydriatic, and in three myotic. The Argyll-Robertson pupil was found five times in one eye and three times in both. Out of thirty cases examined for fundus changes three showed advanced atrophy, five optic neuritis. A certain amount of variation was to be expected in the ocular symptoms, as a patient might show inequality, contraction or dilatation, or irregularity of outline at one time and not at another. Loss of light reflex or accommodation reflex might be present for weeks and then disappear, and these reflexes be found normal.

**Professional Neuroses.**—Dr. Roskam (*Gaz. Méd. Belge*, April 20th), in an article on this subject, concludes that—(1) Professional neuroses is a misnomer, and these diseases should be excluded from the group of nervous maladies since they are muscular affections due to overwork; the muscles affected are those belonging to the group of extensors and abductors; (3) the characteristic lesion is a fibrous centre seated in the muscle in the neighborhood of the tendon; (4) the treatment consists in the careful massage of the part affected.

**The Cure with Sodium Bromide of Habituation to Morphine, Chloral, and Cocaine.**—MacLeod (*British Medical Journal*, April 15, 1899) recommends the following mode of procedure: Having taken the weight of the patient and ascertained the absence of contraindications, sodium bromide is administered in doses of two drachms in solution every two hours for the first two days and of one drachm on the third day. None is given after bedtime on the third day. Three ounces of the drug in all will probably suffice, but more may be administered to induce deep sleep that may continue for five or six days and nights, during which time milk alone should be given. Night and morning the patient should be placed on the commode for evacuation of bowels and bladder, or oftener if there is any sign of soiling the linen. Solid food should be given as soon as it can be taken, and when locomotion is recovered exercise should be encouraged. Morphine or cocaine may be continued the first day in the habitual dose, halved on the second day, and withdrawn or given in small dose on the third day. Chloral may be cut off at once if there is good sleep on the first night. A case may appear well in three weeks, but at least three more weeks should be allowed for convalescence.

**Exaggerations of Treatment in Diabetes.**—In a recent lecture Dieulafoy spoke of the reaction which had taken place against over-treatment in diabetes. He divides the cases into two categories, calling the first the mild (petit) and the second the severe (gros) form. The former includes those in which the quantity of sugar does not exceed 10 to 15 gm. in the twenty-four hours; these have no marked import and may pass unnoticed for a long time, because of the absence of such telltale signs as carbuncles, etc. In the severe form the patient urinates from 100 to 200 gm. or more of sugar. In spite of this enormous loss these patients are not necessarily more threatened than the others, and there are those among them who, without any precautions, stand this sugar loss quite well. Attention is drawn to the coexistence of azoturic with saccharine diabetes. As to treatment, if 25 to 30 gm. of sugar is passed, it is not necessary to resort to the severe régime so often forced upon patients. The chief point is to see to it that the patient does not lose flesh. It is a mistake to restrict the diet to the extent to which it is often done. Antipyrin gr. xv. given morning and night, with bicarbonate of sodium gr. vii.–viii., will show a disappearance from the urine of from 30 to 50 gm. of sugar within thirty-six hours. The speaker prefers, instead of Fowler's solution, the arsenate of sodium in solution of 3 cgm. to 80 gm. of water, of which a teaspoonful is taken at each meal. He also believes that it is not necessary to suppress milk in the dietary because of the lactose it contains, but thinks it should be given. Lactose is not transformed into glucose. In the case of severe diabetes the patient should be allowed to drink freely to wash out the sugar instead of letting it accumulate. If antipyrin does not act well, we must tack about and give arsenate of sodium.—*Gazette Méd. de Strasbourg*, April 1, 1899.

**Treatment of Paralysis Agitans.**—At a recent meeting of the Manchester Therapeutical Society Williamson (*British Medical Journal*, June 3, 1899) pointed out the importance in cases of paralysis agitans of securing sound sleep, as the symptoms are usually worse after a restless night. For this purpose he recommends alcohol or whiskey and hot water at bedtime. Alcohol taken during the day, as well as strong tea and coffee, seems to increase the trembling, while needlework or writing often appears to have the opposite effect. Holding the arms above the head for some time lessens the movements. A warm bath often had a good effect. The bed should not be too soft, and the living-room should be well ventilated, and not too warm. Systematic open-air treatment is important, carriage-drives being advantageous and railway journeys often beneficial. Morphine hypodermically affords relief, but is objectionable in a disease so chronic as paralysis agitans. Hyoscine has proved most useful, but the dose should not be too small. A good formula consists of hyoscine hydrobromate gr. ¼, in chloroform water ʒ vi., the dose being two teaspoonfuls. The drug loses its effect after a time, and should then be intermitted, to be resumed later.

**Acute Diffuse Gonococcus Peritonitis.**—Cushing (*Bulletin of the Johns Hopkins Hospital*, vol. 10, No. 98) reports two cases of gonococcus peritonitis, gives a summary of the literature on the subject, and offers the following conclusions: (1) The gonococcus is capable of causing a specific infectious disease, namely, gonorrhœa, and at the same time other and less specific pathological conditions. (2) There is experimental proof that in certain small animals the gonococcus can set up acute alterations in the peritoneum homologous with the acute septic serositides in man, but differing from these in their tendency to rapid and spontaneous healing. (3) Hitherto there has been wanting conclusive proof that in the peritonitides attendant upon gonorrhœa occurring in women, the gonococcus was solely or chiefly concerned. The inflammations had been variously regarded as mixed infections and chemical inflammations. (4) The cases now reported bring for the first time convincing evidence of the existence of a diffuse, general inflammation of the abdominal cavity caused by the gonococcus. (5) It has been recognized that extension of the gonorrhœal infection from the genital organs to the peritoneum may occur in the puerperal state; a similar sequel is shown to be possible during menstruation. (6) Such ascending forms of gonorrhœa doubtless, under ordinary circumstances, remain localized in the pelvis, and rarely demand surgical intervention in the acute stage. (7) A general involvement of the peritoneum, such as occurred in the two cases related, must be either rare or unrecognized, and may depend upon some specially receptive condition of the serosa or virulence of the organism. (8) The peritoneum is not more immune than are the pericardium and endocardium to gonococcal infection, and, being more exposed, suffers more commonly in women, although the relatively benign course of the disease makes it a rare condition to come to the attention of the surgeon in the acute stages.

MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & CO., 51 Fifth Avenue.

New York, July 29, 1899.

## BRAIN-TUMOR AT THE BASE OF THE SECOND LEFT FRONTAL CONVOLUTION WITH AGRAPHIA AS THE ONLY POSITIVE LOCALIZING SYMPTOM.

IT has long been a matter of discussion whether or not a special centre existed in the cerebral cortex for the function of writing, and evidence has been cited upon both sides of the controversy. The number of cases in which agraphia has been present as the sole or most prominent localizing symptom is exceedingly small, and the anatomico-pathological evidence in this connection is inconclusive. On the other hand, numerous cases have been placed on record in which motor aphasia has existed without agraphia, the lesion involving Broca's convolution solely; while in a number of others the second frontal convolution was also involved and agraphia was associated. A case that would seem to decide the question in the affirmative—in so far as a single case can be considered as affording conclusive evidence—has recently been recorded by Gordinier (*American Journal of the Medical Sciences*, May, 1899), in which with agraphia unassociated with aphasia a destructive lesion was found in the left second temporal convolution. The patient was an intelligent Irish woman, thirty-seven years old, whose father had died of carcinoma of the face, one sister of pulmonary tuberculosis, and another of nephritis. Previously in excellent health, the patient began to fail in strength, and had several attacks of vertigo, without falling, and without nausea or vomiting. A short time later, severe frontal and occipital headache set in, with occasional attacks of vomiting. After three months impairment of vision was noticed and complaint was made of numbness in the right arm. The patient at no time had a convulsion, nor the slightest difficulty in expressing thought by articular speech. The woman recognized and named correctly any object placed before her, and also with her eyes closed any familiar object placed in her right hand. She understood perfectly what was said to her, and she recognized familiar hymns. She was able to repeat words after another, and she spoke voluntarily without the slightest hesitation, and always correctly. With the aid of glasses she could read correctly ordinary-sized print or writing. She recognized numerals at once. She was, however, totally unable to write, although she understood perfectly written language and was able to read to herself or aloud. She could not write voluntarily or form correctly a single letter, nor write from dictation or copy. She held the pen in a perfect manner, and performed the movements of writing, making, however, only a series of united curves. She was not ambidextrous, and could not write with her left hand. There was no indication of paralysis of any of the muscles of the right upper extremity, and the patient had been able previously to write perfectly with the right hand. The pupils were moderately and equally dilated, and responded actively to light and in accommodation. The hemiopic pupillary phenomenon was present. There was no hemianopsia, but there was inflammation of both optic nerves, more intense on the right. The right external rectus muscle was paretic, so that the right eyeball could not be rotated outward, and there was diplopia. The grasp of the right hand was weaker than that of the left. The knee-jerks could not be elicited, even with the most careful reinforcement. Although there was no evidence of syphilitic infection, potassium iodide in conjunction with mercury was administered for six weeks, but without any amelioration of the symptoms. In the interval cerebration had become quite slow. There was further a tendency to fall or to stagger toward the right side. After a further period of six weeks, attended with much suffering, the patient consented to an exploratory operation, and the left Rolandic area was exposed. On removing the button of bone the dura bulged into and through the opening, forming an elastic, slightly pulsating swelling. On incising the dura, a considerable quantity of subarachnoid fluid escaped, with the formation of a hernia cerebri. The opening was enlarged forward, and careful search was made for a lesion, but none was detected. The cortical area exposed by the trephine opening appeared normal. The condition of the patient becoming alarming, the wound was at once closed, drainage being provided for. On emerging from the anæsthesia the right arm was found paralyzed, and the right leg paretic. The patient appeared drowsy and stupid, and complained of great pain in the region of the wound. She rapidly passed into a condition of unconsciousness, with loss of control of the bladder, and a rapid and feeble pulse; and death took place on the second day after the operation.

On post-mortem examination a new growth was found occupying the foot of the second left frontal convolution, distinctly separated from the arm area by the precentral sulcus, which was well developed. The growth was elevated about 0.5 cm. above the surrounding cortex, was slightly irregular in outline, of distinctly firm consistence, and oval in shape. Its longest cortical diameter was 2 cm., and over it the pia was intimately adherent. On section the tumor was seen to extend downward and inward in the centrum semiovale as far as the root of the anterior horn of the lateral ventricle, and forward to near the apex of the frontal lobe, involving almost exclusively the white matter of the second frontal gyrus. The left third frontal convolution was found macroscopically perfectly normal throughout its whole extent, as was

also its associated centrum ovale. The centrum ovale of the first frontal convolution was infiltrated by the growth toward its ventral part. On histological examination the tumor was found to be a glioma of rapid growth.

---

## ON THE RESPECTIVE PARTS TAKEN BY THE URINE AND THE FÆCES IN THE DISSEMINATION OF TYPHOID FEVER.

Without quibbling as to whether typhoid fever is "contagious" or not, it is generally agreed that the disease is transmissible or communicable from the sick to the well though the intermediation of the bodily discharges. It is no longer contended that the disease may arise *de novo* from filth and fermentation, but it has been demonstrated conclusively that there can be no typhoid fever without the presence of the typhoid bacillus. The most common mode of dissemination is through water contaminated by the discharges of typhoid-fever patients, and in the past the stools have been held almost exclusively responsible for such contamination. Recent investigation has, however, shown not only that the bowel is not the exclusive seat of the lesions, but that the intestine may escape and other structures and organs be attacked. It has also been found that typhoid bacilli may be eliminated in the urine.

As the result of a study of the excreta from cases of typhoid fever and an analysis of the literature upon the subject, Horton Smith (*The Lancet*, May 20, 1899) concludes that the stools of a typhoid-fever patient, unmixed with the urine, contain typhoid-fever bacilli in fair quantities, demonstrable by present methods, up to about the beginning of the third week. After this date the number begins rapidly to diminish, so that existing methods no longer avail, as a rule, to find them. If, however, a relapse occurs, it may be preceded by a recrudescence of the typhoid bacilli, which can then be found again in the fæces, but during the greater part of the relapse itself and through convalescence the typhoid bacilli cannot be found in the stools. It can no longer be doubted that typhoid bacilli occur in the urine of typhoid-fever patients, probably in about twenty-five per cent. of all cases. For the most part, though present in such numbers as to be demonstrated bacteriologically with the greatest ease, they are not present in sufficient quantities to alter the naked-eye appearance of the urine. In a smaller proportion of cases, however, probably about five per cent. of all typhoid-fever cases, the urine is rendered turbid by their presence. They are nearly always in pure culture. They occur first late in the disease, rarely, if ever, before the third week, and they may make their first appearance during convalescence. They generally remain present for some considerable time, for some weeks or even months. The character of the urine does not assist in diagnosticating the condition, unless, of course, it be rendered turbid by the bacilli. The urine may contain no albumin, although it often contains but a trace, and sometimes a good deal. It sometimes contains pus, but all of these conditions occur quite apart from the presence of typhoid bacilli in the urine. The prognosis in a given case is not rendered more grave by the presence of typhoid bacilli in the urine.

These observations are of not a little practical importance, and they teach that the same care should be exercised in the disposal of the urinary secretion as in that of the fecal discharges of typhoid-fever patients. If such precautions were generally and rigorously observed, the prevalence of typhoid fever would be much reduced, and the disease rendered sporadic, instead of endemic or epidemic as it is in many communities.

---

## MENTAL SUGGESTION.

Every physician is well aware of the potent influence for good or ill that the mind exerts over the body in sickness. In health, too, the effect of mental suggestion is with many persons powerful to an extraordinary degree. Upon this notorious psychological fact the Christian Scientists and faith curers of all kinds base their treatment, and in virtue of some indisputable cures brought about by these means have been so long able to gull the public into the belief that their healing powers are effective in any case of disease or injury. Patent medicines and quacks owe their success to precisely identical reasons. If an individual has faith in a medicine or in a treatment, he will assuredly derive more benefit from that medicine or treatment than if he were sceptical as to its merits. There can be little doubt that the sympathetic physician is the one best calculated to lead his patient to recovery. Again in many diseases the good that may be wrought to the sufferer by the agency of mental suggestion is undeniable. Prof. J. M. Baldwin, referring to this fact in connection with insomnia, says: "In experimenting upon the possibility of suggesting sleep to another, I have found certain strong reactive influences upon my own mental condition. Such an effort which involves the picturing of another as asleep is a strong auto-suggestion of sleep, taking effect in my own case in about five minutes if the conditions be kept constant. The more clearly the patient's sleep is pictured the stronger becomes the subjective feeling of drowsiness. An unfailing cure for insomnia, speaking for myself, is the persistent effort to put some one else asleep by hard thinking of the end in view, with a continued gentle movement such as stroking the other with the hand."

Dr. E. C. Spitzka, of New York, has recently given some really remarkable instances of the power of mental suggestion. He cites the well-known fact that the mortality from wounds and diseases in a defeated army compared with a victorious army is as 4 to 3, and even as 3 to 2. He also refers to the incontrovertible fact that persons in robust health have been known to die apparently of starvation after being without food for from three to five days. Dr. Spitzka is of the opinion that these individuals did not die of actual starvation, but from the psychical effects of hunger. The proof of this contention lies in the fact

that persons have been known to fast of their own free will for more than forty days without injuring their constitutions to any appreciable extent. Many examples establishing the truth of this statement might be given, but it will be sufficient to quote one from Dr. Spitzka's paper. He says: "In the graver forms of hysteria, when loss of sensation occurs in exactly one-half of the body, you can lay a piece of tinted paper on the sensitive side; then suggesting it to be a mustard plaster, a red area will appear on the corresponding unsensitive side. Blisters of such a character that scars have permanently remained from them have been produced in similar cases by the same method." The medical profession, it appears more than likely, have not as yet wholly appreciated the advantages to be derived from the employment of mental suggestion.

## News of the Week.

**To Inspect the Cuban Quarantine Service.**—Passed Assistant Surgeon Milton J. Rosenau, of the marine hospital service, has been detailed to inspect the quarantine service on the Cuban coast.

**A New English Naval Hospital** is to be erected at Chatham. The building will be of brick with stone facings. It is thought that the old hospital will be converted into barracks for the marines.

**The Italian Lynching.**—The trouble which ended in the lynching of five Italians at Tallulah, La., on Thursday night of last week originated in the killing of a goat belonging to one of the dead men by Dr. Hodges of that place. In revenge the Italians attacked the doctor and shot him in the abdomen, and they in turn were lynched by an infuriated mob of Dr. Hodges' friends.

**A Hospital for Consumptives in Chicago.**—A dispatch to the New York *Times* from Chicago says that a well-known and wealthy business man of that city, whose name is withheld for the present, is going to use part of his large fortune in erecting a hospital for incurable consumptives, as a memorial of his daughter who died recently of pulmonary tuberculosis after great suffering.

**Typhoid Fever at Flushing.**—Typhoid fever has appeared in Flushing, L. I., an average of one new case a day having been reported during the past two weeks. Heretofore the village has been almost free from the disease. An impure water supply is said to be the cause of the outbreak. For the past three months the pumping-station has not furnished sufficient water to supply the demand, and it has been necessary to use water from a small pond near the station to supply the deficiency.

**A Physician Assaulted for Performing a Work of Mercy.**—Dr. Froehlich, of this city, was brutally assaulted on Sunday night by striking motormen of the Second Avenue trolley road, because he bandaged the head of a non-striker who had previously suffered at their hands. He was told by a passer-by that a man with his head cut was in the next block, and going there, he found a man in the uniform of a motorman with a long gash in his scalp. He stopped the bleeding and bound up the wound as best he could for the time, and while so engaged was warned by one of a crowd of strikers that he had better leave the man alone if he valued his own health. He finished bandaging the wound and then started for his home, but had not gone far when he was struck on the head with a brick, and soon eight men rushed on him, threw him down, and beat him severely before the police arrived.

**The Yellow-Fever Outbreak at Santiago** has been overcome, only one case of even suspected yellow fever having been reported in nearly two weeks. At Havana a case is discovered from time to time, but there is less in the city now than there always was, even in midwinter, under the old régime of filth. An official report dated July 18th has been issued at Panama declaring the city entirely free of yellow fever.

**The Red Cross in Cuba.**—During the past three months twelve orphan asylums, accommodating about twelve hundred children, have been established by the Red Cross Society in the provinces of Havana, Matanzas, and Santa Clara. Most of the inmates are waifs from three to fifteen years of age, and are the children of reconcentrados starved to death by Weyler's orders. Miss Barton estimates that there are in the neighborhood of fifty thousand of these reconcentrado orphans running wild in the towns of Cuba.

**Poisoned Tea at Bellevue.**—Several patients in one of the convalescent wards at Bellevue were the victims recently of accidental phosphorus poisoning. One of the patients, in reaching for a glass, overturned a box of matches, throwing half its contents into a can of tea which was just to be served to the inmates of the ward. The patient whose duty it was to distribute the tea noticed the matches floating about, but thought nothing of it, and merely fished them out and went on with the distribution. Soon after drinking the tea, several of the patients became very sick, but the cause of the trouble was quickly discovered, and prompt medical assistance averted any serious consequences.

**Diphtheria at the Willard State Hospital.**—The State board of health reported on Friday of last week that there had been thirty-four cases of diphtheria at the Willard State Hospital, and that the institution was under quarantine. The disease was of a mild type, and no deaths had been reported. All the sick are being treated with antitoxin, and all the other patients in the hospital are being given injections of small quantities of the antitoxin, so as to make them immune. A bacteriological examination showed that many of the physicians, nurses, servants, and others in the institution had diphtheria bacilli in the mucosa of their upper air passages and mouths.

**Artificial Fruit Syrups.**—Fifteen confectioners and druggists were recently haled to the Essex Market police court to show cause why they should not be pun-

ished for violation of the revised statute which forbids the adulteration of food and food products, in that they had sold adulterated syrups in flavoring of soda water. As these were the first cases under the new law, the magistrate dismissed the men with a reprimand. The arrests were made at the instance of the fruit-dealers. On July 25th fourteen more soda-water sellers were arraigned for the same offence. They pleaded that they had bought the syrups in good faith from wholesale dealers, and did not know they were artificial. They were dismissed with a warning. After September 1st the syrups used for soda water will be subjected to the scrutiny of the health department, and the small venders who peddle lemonade from carts, as well as the large houses which dispense soda water from pretentious fountains, will be held to a strict obedience of the new law governing the adulteration of syrups. The selling of adulterated and unwholesome syrups is made by the Ford act a misdemeanor, punishable by a fine of not more than $250, or by imprisonment of not more than six months, or both. Much of the so-called lemon syrup used in lemonade and soda water contains not a drop of lemon juice, but is made of various acids, chief of which are tartaric and citric. The vanilla, strawberry, raspberry, and orange syrups are also in many cases innocent of any admixture with the juices of the fruits whose names they have borrowed.

**More Surgeons Needed at Manila.**—Surgeon Woodhull at Manila is reported to have stated that the increased military forces in the Philippine Islands will necessitate the employment of forty additional surgeons, but his recommendation to that effect has been disapproved by General Otis. There are nearly three thousand soldiers in the hospitals in Manila, San Fernando, and elsewhere. There are also two hundred and seventy-five sick in quarters in Manila.

**Famine and Plague in India.**—A dispatch from Bombay says that the partial failure of the monsoon has occasioned grave anxiety. The rainfall has been injuriously excessive in Bengal and the northwest provinces, but in the Deccan, Berar, Gujerat, and some of the central provinces there has been almost no rain. The situation in Western India is already critical, and a failure of the crops with a consequent recurrence of the famine is gravely threatened. The plague is again increasing in Poonah, where there were one hundred and sixteen cases and eighty-two deaths reported on July 23d.

**Contention between a Governor and a Dental Society.**—The governor of Connecticut and the members of the State Dental Association are at loggerheads over the appointment of a member of the State dental commission. Recently the association sent a request to four of the five members of the Connecticut State dental commission to resign at once because the association objected to the fifth member of the commission, who had been expelled from the association and who had secured his appointment to the commission by political influence and not by merit. Governor Lounsbury appointed the objectionable member, and stated recently that he did not recollect receiving any protest against the appointment at the time. In reply to this several members of the association make affidavit that they protested to the governor in person.

**Orrhotherapy of Snake Bite.**—A correspondent of the London *Times* tells of a man in Allahabad, already in a state of collapse following poisoning by a snake bite, who was cured by an injection of Calmette's serum.

**A Hospital Struck by Lightning.**—During a severe storm that passed over this city last Friday the J. Hood Wright Memorial Hospital in Harlem was struck, and some of the inmates were stunned, but none was seriously injured.

**Prof. Charles F. Chandler** of Columbia University, and formerly professor of chemistry at the College of Physicians and Surgeons, has been elected president of the Society of Chemical Industry of England. Dr. Chandler has served as chairman of the New York section of the society, but is the first American to be elected president of this, or we believe of any other, English scientific society.

**Dr. Max Breuer,** of Buffalo, has, according to the Paris *Figaro*, been nominated a Chevalier of the Legion of Honor in recognition of services rendered a French sailor at the risk of his own life. Dr. Breuer was the surgeon on a Hamburg-American line steamer, and in response to a call from a petroleum vessel he braved a dangerous sea to attend an injured Frenchman aboard the latter steamer, saving the man's life by amputating his arm.

**Colchicum Poisoning.**—Some negro ball players at Eufaula, Ala., were recently celebrating their victory over a visiting club, and one of the members, who was a porter in a drug store, stole what he thought was a bottle of wine and presented it as his contribution to the festivities. Seven of the revellers drank freely of the beverage, and soon paid for their indulgence by vomiting, pain, and prostration. At the last accounts three of the negroes were dead and the remaining four were not expected to recover.

**A Plague of Mosquitoes.**—According to a story, published recently in the *Sun*, from American Falls, a Snake River town in Idaho, the people there were being driven from their homes by mosquitoes. Swarms of the insects made life unbearable, and people were forced to take to the mountains as fast as possible in order to escape absolute torture. On Sunday an attempt was made to hold services in the church, but the mosquitoes broke up the meeting, and preacher and congregation fled from the building. A baby is said to have died in consequence of the many stings given to it by the insects.

**Vegetable Cancer.**—Dr. Bra, of France, whose claim to the discovery of a cancer germ was recently noticed in these columns, has been conducting a series of experiments to determine the relation between certain vegetable neoplasms and human carcinoma. Having found micro-organisms similar to the alleged parasite of cancer in diseased wood, he was led to in-

oculate several trees with cancer cultures, and claims to have in this way started a morbid process in the vegetable organism which, in one instance, caused the death of the tree. It might be rash to dispute facts or to deny the conclusions of this ingenious investigator, but he will certainly have to furnish strong evidence to convince a skeptical world of the validity of his claims.

**The First Case of Yellow-Fever Inoculation.**—Mr. Oscar F. Lackey, the first yellow-fever patient in this country to be subjected to serum treatment, was discharged cured from the quarantine hospital on Monday of this week.

**Medical-Practice Laws in Havana.**—A meeting of the Havana Academy of Science was recently held to protest against the order permitting physicians who use interpreters in their examinations to be admitted to practice there.

**Multiple Lightning Fatalities.**—During a thunderstorm in Berlin on Sunday last forty persons who were leaning against a wire railing at the Charlottenburg cycle track were struck by lightning. Three were killed and twenty were severely injured.

**A French Neurological Society.**—A Neurological Society was formed in Paris on June 8th. Professor Joffroy is president, Professor Raymond vice-president, M. Pierre Marie general secretary, M. Henry Meige secretary of sittings, and M. Souques treasurer. The society will issue the *Revue Neurologique*, which is to be its official organ and which will appear on the 15th of each month.

**A Lively Disciplinarian.**—An Indiana citizen, one hundred and six years old, who evidently believes that as the twig is bent the tree will grow, recently chastised his son, aged seventy years, because the latter came home drunk and abused his wife. The judge fined the young sower of wild oats for his condition, but took no judicial cognizance of the father's exercise of his parental prerogative.

**The Orange Training-School for Nurses** has decided to adopt an alternative course of instruction for those pupils who prefer not to engage in private nursing before graduation. In one course the pupils will receive no compensation, but will be required to pay a fee of $150 a year, the course being of two years' duration. Under its terms the women will not be required to do private nursing. In the alternative course the present two-year term will be lengthened to three years, and nurses who enter it will receive compensation as heretofore after the first six months' service and in addition will receive a bonus of $75 on graduation. In this course the nurses will do private nursing as heretofore.

**The Perils of a London Medical Practice,** at least in the East End, are seemingly comparable to those in a Western mining town or even in New York itself during a street-railroad strike. A Dr. Stonham, who is the parish doctor to a large section of the East End of London, was recently attacked, when leaving a house where he had been called to see a patient in the middle of the afternoon, by five men, thrown down, and robbed of his watch and money. In his complaint to the authorities he says that a few weeks previously another physician, practising like himself among poor patients, was knocked down, brutally assaulted, and robbed at one o'clock in the day in the main thoroughfare.

**Major William Duffield Bell,** of the Seventy-first Regiment, who was the regimental surgeon in the Santiago campaign, has resigned.

**A Prolific Family.**—A French-Canadian woman, twenty-eight years of age, living in Maine, recently gave birth to her third pair of twins in three years. The father of these children, who is thirty years of age, was a twin himself and so was his wife.

**A Memorial of Sir Thomas Browne.**—A movement is on foot for the erection in Norwich, England, where he resided for a period of forty-six years, and in which city he died in 1682, of a memorial statue of Sir Thomas Browne, the author of "Religio Medici." While excavating a grave in the chancel of St. Peter's some years ago, a coffin was broken open, which proved to be that of Sir Thomas Browne, the skeleton being in good preservation, and the hair of the beard very profuse.

**Changes at the Johns Hopkins.**—At the commencement of the Johns Hopkins University, held on Tuesday, June 13th, there were thirty-three graduates from the medical school, two of whom were women. The changes in the medical faculty announced for next year were as follows: J. Whitridge Williams, associate professor, will be professor of obstetrics; Lewellys F. Barker, associate professor of anatomy, will be associate professor of pathology; Ross G. Harrison, associate, will be associate professor of anatomy. Several new assistants were also appointed, also the internes and externes of the hospital, as well as the resident house officers.

**Obituary Notes.**—Dr. Robert Horner, of Gettysburg, Pa., died in that place on July 1st. He was born in Gettysburg on October 17, 1825, and was graduated in medicine from the University of Pennsylvania in 1849. He served for a short time during the Civil War as acting assistant surgeon of the United States army in the field hospitals of Gettysburg.—Dr. Regolo di Moise, an Italian physician, who had lived in this city a little over a year, committed suicide by swallowing carbolic acid on July 19th.—Dr. Jacob Bossert, of Washingtonville, Ohio, died July 19th at the age of seventy-one years. He was a graduate of the Western Reserve Medical College in 1837. He is survived by a widow, four daughters, and one son.—Dr. F. M. Endlich, formerly of Reading, Pa., died by suicide on July 17th at Tucson, Ariz., at the age of forty-eight years.—Dr. Charles Howard Hill died at Philadelphia on July 18th, the age of eighty-five years. He was a graduate of Jefferson Medical College in the class of 1835, and had been engaged in the practice of his profession for more than sixty years.

# Reviews and Notices.

Les Glycosuries Non-Diabétiques. Par Germain Roque. Professeur agrégé à la faculté de médecine, etc. Paris: J. B. Baillière et fils. 1899.

This little brochure of the series of "Les Actualités Médicales" treats in an entertaining manner of glycosuria due to other causes than true diabetes. Treatment is subdivided to cover the arthritic, the digestive, the nervous, and the puerperal forms. There is a bibliographical index.

Transactions of the American Climatological Association for the Year 1898. Philadelphia: Printed for the Association.

This, the fourteenth volume of the series, well maintains the high standard of excellence reached by the former ones. Some of the contributions are of especial interest, more particularly those treating of diseases of the organs of respiration, to which indeed the book is chiefly devoted.

Transactions of the Medical Society of New Jersey, 1898.

This volume contains many excellent essays. Dr. William Pierson writes on "The Umbilical Cord"; Dr. H. B. Costill, on "Uterine Displacements"; Dr. J. C. Applegate, on "Regression vs. Progression"; Dr. S. A. Twinch, on "The Diagnosis and Treatment of Pott's Disease." The book is well printed and embellished with unusually good diagrams.

Radioscopie et Radiographie Cliniques. Par le Dr. L. R. Régnier, Chef du laboratoire d'électrothérapie et de radiographie de l'hôpital de la Charité. Paris: J. B. Baillière et fils. 1899.

This volume continues "Les Actualités Médicales." It has ninety-two pages in boards over, and is illustrated with eleven woodcuts. It covers fairly well the technique and clinical side of radioscopy.

Practical Materia Medica for Nurses, with an Appendix containing Poisons and their Antidotes, with Poison-Emergencies; Mineral Waters; Weights and Measures; Dose-List; and a Glossary of the Terms used in Materia Medica and Therapeutics. By Emily A. M. Stoney, Graduate of the Training-School for Nurses, Lawrence, Mass.; late Head-Nurse, Mercy Hospital, Chicago, Ill.; late Superintendent of Training-School for Nurses, Carney Hospital, South Boston, Mass.; Author of "Practical Points in Nursing." Philadelphia: W. B. Saunders. 1899.

As the title suggests, this volume is meant only for nurses, and is not overburdened with scientific terms and confusing descriptions. The drugs are taken up alphabetically, and this arrangement makes the book especially a ready-reference volume such as one on active duty in the ward of a hospital will duly appreciate. The author has consulted the leading authorities in her compilation, and has been aided in the revision of her completed work by a physician.

Diseases of the Ear, Nose, and Throat, and their Accessory Cavities. By Seth S. Bishop, M.D., LL.D., etc. Second edition, revised and enlarged. Illustrated. Philadelphia, New York, Chicago: The F. A. Davis Company. 1898.

The second edition of this work represents a considerable enlargement upon the first both in text and number of illustrations. The book is improved in many ways, and some of the illustrations, especially the colored ones, are very graphic, making the work useful to the general practitioner as well as the specialist. The author in one place speaks of a ten-percent. solution of carbolic acid, which is an impossibility if we remember our chemistry correctly. A saturated solution of carbolic acid is one in sixteen.

The new chapters have added interest to the work, and that on the relation of life insurance to diseases of the ear, nose, and throat discusses an important subject in a practical way. The surgery of the mastoid is covered satisfactorily, but nothing novel is offered. On the whole, we may say that the volume makes a good text-book for the incipient specialist, and a useful work of reference when he is full-fledged.

Thirteenth Annual Report of the State Board of Health and Vital Statistics of the Commonwealth of Pennsylvania. Transmitted to the Governor, December 1, 1897. William Stanley Ray, State printer of Pennsylvania. 1898.

This annual report is comprised in two somewhat bulky volumes, and is exceedingly thorough and comprehensive. That portion of the work treating of the water supply is, under the state of affairs prevailing in Philadelphia, of more than ordinary interest, and is, besides, extremely well supplied with illustrations and diagrams. Dr. Thomas Turnbull, of Pittsburg, contributes an instructive paper on the monetary loss to cities from typhoid fever, pointing out that the time is fast approaching when municipalities will be held responsible for negligence in sanitary matters. The second volume is devoted principally to meteorological observations.

A Text-Book on Practical Obstetrics. By Egbert H. Grandin, M.D., etc., with the collaboration of G. W. Jarman, M.D., etc. Second edition, revised and enlarged. Illustrated with 64 Full-Page Plates and 86 Illustrations in the Text. Philadelphia, New York, Chicago: The F. A. Davis Company. 1898.

We have in this volume the second edition of a work which when in its former edition created a favorable impression as a practical treatise in its special field. The present volume is considerably enlarged and has been revised so as to bring it up to date, and a number of illustrations have been added. The aim of the authors has been evidently to furnish a practical handbook to serve as a guide for those who are working in the branch of obstetrics, and in this they have succeeded. The whole subject of normal and abnormal labor is covered in a satisfactory manner, without much bibliography and references as to "who did this or that first," and in that part of the work devoted to obstetric surgery we find an interesting chapter upon symphyseotomy. Perhaps many operators would not agree with the authors' apparent preference for Ayer's method of doing this operation, on account of the objection in general to cutting in the dark to a certain extent. A few inaccuracies mar the text, such as on page 109 in parentheses thus: "(using the Latin word *mento* for chin)." Hardly "*mento*." The second edition has undoubtedly added to the good impression which the book had already created, and the illustrations are all good as illustrations, but the didactic value of some of the photographic reproductions is very questionable.

Twentieth Century Practice. An International Encyclopædia of Modern Medical Science. By leading authorities of Europe and America. Edited by Thomas L. Stedman, M.D., New York City. In twenty volumes. Volume XVI., Infectious Diseases. New York: William Wood & Company. 1899.

As this encyclopedic venture approaches its completion it seems rather to improve in quality than otherwise. To be sure, the subject of infectious diseases has been extensively investigated of late years, and there is much new material from which writers on these interesting topics may draw inspiration. The subjects treated in this volume include lobar pneumonia, cerebro-spinal meningitis, dysentery, yaws, erysipelas, simple continued fever, relapsing fever, and typhoid fever. The authors' list contains such names as A. H. Smith, J. W. Brannan, and J. S. Thacher of New York, L. B. Edwards of Richmond, A. Netter of Paris, O. Kiliani of New York, A. Sodré of Rio de Janeiro, L. Popoff of St. Petersburg, H. A. A. Nicholls, of Dominica, and E. Ziegler of Freiburg. The last-named writer contributes a most excellent article on "inflammation," but just why it finds its place in this volume does not appear, since all inflammations cannot be looked upon as due to infectious or bacterial noxæ. The introductory article upon lobar pneumonia, by Dr. Andrew H. Smith, brings out much that is novel and important in its bearing upon this disease, and is an effort which will undoubtedly attract wide attention. The last article in the present volume is by no means the least. Dr. John W. Brannan, of New York, has discussed in a masterly way in a space of one hundred and fifty-five pages the symptomatology and the treatment of typhoid fever.

An extensive bibliography accompanies each contribution. The editorial and publishing departments have left nothing to be desired.

# Society Reports.

## THE MEDICAL SOCIETY OF NEW JERSEY.

*One Hundred and Thirty-Third Annual Meeting, Held at Allenhurst, N. J., June 27, 28, and 29, 1899.*

C. R. P. Fisher, M.D., of Bound Brook, President.

*First Day—Tuesday, June 27th.*

Almost all of the afternoon session, held on the first day, was devoted to routine business. The meeting was called to order by the president, Dr. C. R. P. Fisher, of Bound Brook, at 3:30 P.M., in the parlor of the Allenhurst Inn, and the session was opened with prayer by the Rev. Dr. Striker.

**Committee on Bovine Tuberculosis.**—Dr. Charles Young, of Newark, presented the report of the committee appointed last year to secure suitable legislative action regarding the control of bovine tuberculosis. He stated that the legislature of New Jersey had enacted a law to prevent the importation of tuberculous cattle into that State. It provided, among other things, that cows imported into the State must be accompanied by a certificate from a duly authorized veterinarian, stating that they had been subjected to the tuberculin test. The railroad companies were forbidden to carry cattle without such certificate. If cattle were imported, the State tuberculosis commission should cause them to be subjected to the tuberculin test, and animals giving indications of tuberculosis should be slaughtered, and no indemnity should be paid. The penalty for the first offense was a fine of from $25 to $200, and for the second offense imprisonment for a period of from one to six months in addition to the fine. The legislature appropriated for the use of the State commission on tuberculosis the sum of $10,000, instead of $5,000 as hitherto.

**Committee on Pollution of Streams.**—Dr. Henry Mitchell, of Asbury Park, presented the report of this committee. It stated that a law had been enacted, giving power to local boards of health to prosecute those guilty of polluting the Passaic River above the Great Falls, and to apply to the court of chancery for an injunction. The report also referred to certain legislation by which all municipalities were forbidden to allow sewage to be discharged into streams except in accordance with plans that had been approved by the State sewerage commission.

**President's Address: The Century's Progress in Medicine.**—The evening session was opened with the annual address, which was delivered by Dr. C. R. P. Fisher, the president. He said that at the beginning of this century auscultation was unknown, although introduced to the profession in 1819. The discovery of albuminuria by Richard Bright, in 1827, and of renal casts in 1837, had given a great impulse to the study of the diseases of the kidney. It was difficult now to realize that the hypodermic syringe had been absolutely unknown sixty years ago. The invention of the aspirator in 1869 was an important addition to the physician's armamentarium. The influence of Virchow's theory of cellular pathology and of Pasteur's germ theory had been enormous, but needed only passing mention, as it was still fresh in our minds. In 1880, when O'Dwyer had first demonstrated that in many cases laryngeal stenosis could be relieved without resorting to tracheotomy, it became possible to save many lives that would otherwise have been lost. It had not been until the present century that diphtheria had been accurately observed, studied, and classified as an entity. This had been done about 1825. The treatment of diphtheria with antitoxin, he felt sure, would shine out in time as one of the greatest medical triumphs of this century. There was but little doubt that there was a brilliant future for serum therapy in general, although as yet the antitoxin treatment of diphtheria had alone proved of signal value. Referring to the progress made in surgery, the speaker said that there could be no doubt that the advance in surgery during the nineteenth century had been greater than in any ten previous ones—not that there were not many great surgeons in the past, but those were the days of "laudable pus" and hospital gangrene. In 1848, when Dr. Henry Bigelow had read his paper on "Surgical Insensibility during Operation by Inhalation," one of the greatest of boons had been conferred upon the human race. It was impossible now for us to appreciate the furor which it had excited. But while general anæsthesia had been of enormous value to the surgeon, it had many drawbacks. The discovery of anæsthesia had immensely broadened the field of surgery, yet the fact remained that the mortality from operations of any magnitude was excessive. The glory of being the pioneer in the field of antiseptic surgery must ever be awarded to Sir Joseph Lister. Although methods had changed, and might still further change, the principle would endure —anæsthesia and surgical cleanliness would ever remain the brightest stars in the surgical firmament of the nineteenth century, and it would be impossible to say which was the greater. The revival of the operation of symphyseotomy should be noted as a distinct advance, for when done under modern antiseptic precautions it was comparatively free from risk. Reference was then made to state medicine. Dr. Fisher said that hygiene, or preventive medicine, dated from the earliest times, the Mosaic laws being the most stringent; but it had been only in recent years that governments had endeavored to enforce properly the sanitary laws. At the present time, our health boards were clothed with almost autocratic power. Michigan, Massachusetts, and New Jersey now possessed sanitary codes which were models, according to our present knowledge. One of the logical sequences of the advances of medicine in this century had been the rapid growth of specialism; the field had grown so broad that it was a physical impossibility to keep pace with the progress made in the various branches. The true specialist was born, not made; yet, other things being equal, the man whose knowledge of medicine was the broadest would make the best specialist. The raising of the standard of medical education augured well for the progress to be made in the medicine of the twentieth century.

**Treatment of Abortion.**—Dr. J. S. Baer, of Camden, read a paper on this subject. He said that he had adopted as a maxim in practice that "an empty uterus is a safe uterus, and safe only when it is empty." The subject was considered by the author under three heads, viz.: (1) Threatened abortion; (2) inevitable abortion; (3) incomplete abortion. In the first class of cases the patient should remain in bed in the recumbent position and keep absolutely quiet, and morphine should be given as required. The fluid extract of viburnum prunifolium had proved useful in many cases. In the second class the tampon was useful if properly applied; it not only diminished the chances of sepsis but spared the woman much loss of blood, and by exciting uterine contraction brought the case to a speedy and happy conclusion. Before the tampon was applied the external genitals should be thoroughly scrubbed and cleansed, and then, through a bivalve speculum, two strips of gauze, three inches wide and one or two yards long, should be introduced, one on either side of the cervix. A strip of cotton, twelve inches long, squeezed dry from a creolin solu-

tion, should next be placed in the vagina, and then some dry cotton placed on top of it. A T-bandage completed the dressing, and the patient could then be left with perfect safety from hemorrhage for twenty-four hours. This tamponade might be repeated, if necessary, for another period of twenty-four hours, when, if abortion had not been completed, instrumental delivery should be resorted to. In cases of incomplete abortion the curette should be used; the finger was dangerous, not only because it was difficult to sterilize it, but because the finger could not be introduced up to the fundus, in such cases, without the use of unwarranted force. He preferred to use an instrument known as the curette forceps, invented by Professor E. F. Baer, of Philadelphia. The curetting should be followed by antiseptic irrigations and by packing. Ergot should not be administered until the uterus had been completely emptied, but after this had been accomplished it materially favored the contraction of the uterus and diminished the danger of septic infection. Antiseptic vaginal douches should be used. Not a single case of abortion should result fatally if seen before infection had taken place, or if seen reasonably early and treated in the manner just described.

Dr. W. H. Ireland, of Camden, said that in more than one instance he had observed serious results from leaving in a tampon for twenty-four hours. As the majority of abortions were induced usually by the introduction of the nozzle of a syringe, a slate-pencil, or a hair-pin, the opportunities for early infection were exceedingly good. For this reason it seemed to him dangerous to leave in a tampon so long a time.

Dr. Baer replied, that he had not advocated this use of the tampon except for cases seen before infection had taken place; when there were fever and fetor, no time should be lost in cleansing the uterus, removing all odor, and packing the cavity with antiseptic gauze. He had allowed the tampon to remain for a period of twenty-four hours in more than one hundred instances, without observing the slightest harm therefrom—indeed, he believed tamponing at long intervals inflicted less traumatism on the uterus.

**Epilepsy.**—Dr. L. L. Hand, of Leesburg, read a paper with this title. He said that the cause of essential epilepsy was thought to be a degenerative process in the brain, consequent upon heredity or congenital disease. Of fourteen hundred and fifty cases observed by Gowers, four hundred and twenty-two had begun before the age of ten years, and three-fourths of the whole number before the age of twenty years. When the disease developed in adults it was apt to be due to a local lesion. According to Gowers, heredity figured in forty-five per cent. of the cases. In making the differential diagnosis the greatest difficulty was experienced in distinguishing between epilepsy and hysteria. The pathology of epilepsy was as little understood now as it had been twenty years ago. In a recent study of eighteen cases of epilepsy at the Ohio hospital for epileptics, the constant association of an enlarged thymus had been noted. In considering the question of treatment, the speaker said that when an aura preceded the epileptic seizure, probably the best method of preventing an attack was by the inhalation of nitrite of amyl. Chloral, in doses of ten or fifteen grains, should be given by the mouth either alone or combined with the bromides. The daily life should be regulated, the patient being given moderate exercise in the open air. Tea, coffee, and stimulants should be excluded from the diet. The quantity of food taken must be moderate, and constipation should be carefully avoided. Acetanilid, alone or preferably combined with bromides, would be found useful. The use of antipyrin at night, in doses of five grains, was highly commended. When bromides were administered a saline cathartic should be given every few days. Despite the advances in surgery and in cerebral localization, the surgical treatment of epilepsy had not yielded very brilliant results. Proper employment, together with skilled medicinal treatment, would probably give the best results. The epileptic colony was apparently the ideal method. This country, aggressive in everything else, had been slow in this field. Ohio, in 1893, had made the first attempt; New York had opened its colony in 1895; Massachusetts had begun its work in 1898, and New Jersey had made its beginning in November of last year.

Dr. E. W. Hedges, of Plainfield, reported three cases of apparently incurable epilepsy, that had been promptly relieved by measures directed to correcting eye-strain.

**A Portable Electro-Magnet.** — Dr. Walter B. Johnson, of Paterson, exhibited a perfected electro-magnet of his invention. It was intended to be used in connection with the direct incandescent electric-light current for the purpose of removing pieces of steel which had entered the eyeball. The core of the magnet was made of the finest grade of Swedish iron, which had been re-annealed. It measured seven and one-half inches and weighed eleven ounces. The core could be easily removed from the spool for sterilization. The spool was made of brass, and was three inches long. It was wound with two pounds and ten ounces of No. 27 wire. The resistance was 205 ohms. The advantages claimed were its portability and its convenience wherever there was a direct electric-lighting system. It was not applicable to the alternating system. The pulling strength of the magnet was six and one-fourth pounds, and its cost was $15, far less than other magnets of the same strength.

**The Diagnosis and Management of Pleurisy with Effusion.**—Dr. Louis Faugères Bishop, of New York, read a paper with this title. He said that in all chest diseases it was a safe rule to make examinations at short intervals with a special view to determine, by exclusion, the presence or absence of pleuritic effusion. The cause of the effusion might be in the pleura itself, or result from other conditions giving rise to dropsy in other parts of the body. Cardiac disease did not usually cause effusion until the kidneys had become involved, either by congestion or inflammation. The pleura seemed better able than the peritoneum to take care of itself after the first attack of inflammation. The importance of a pleuritic effusion depended primarily upon the amount. The diagnosis of fluid in the pleural cavity depended upon its physical characteristics as compared with those of the surrounding tissues. Of all the physical signs, flatness on percussion was the most constant, but the sensation of resistance conveyed to the percussing finger was also an important indication. According to his experience, bronchial breathing was as often found as the absence of breath-sounds, and the percussion note was often tympanitic instead of flat. When the breath-sounds were not absent, they had a peculiar character of their own. The advantages of the exploratory puncture were those of a certain means of diagnosis; the danger was from septic infection. The pain of making the puncture was trifling if the needle was introduced with a steady thrust. The dry-diet theory of treatment the speaker likened to a tank of water placed on the bank of a stream; the stream was ready to receive the water in the tank at any time that it might be set free, but no amount of dredging of the stream or changing its volume would have any effect on the water in the tank. The first thing to insist upon was absolute rest and moderate diet; the next thing was to sustain the heart's action. The close connection of the pleura with the nervous system was sometimes strikingly illustrated in individual

cases. Owing to the mechanical conditions present in the thorax it was possible to remove the fluid, even though the puncture happened to be made above the level of the fluid. Of all the devices for aspiration, he preferred the Dieulafoy instrument, and used with this a trocar of about the size of a knitting-needle. The point of election for the puncture was two inches below the lower angle of the scapula. It was a good plan to explore with a fine needle before introducing the larger instrument. As there was always danger of syncope, a stimulant should be administered just before performing thoracentesis.

**The Diagnosis of Insanity; Its Methodology.**—Dr. J. Leonard Corning, of New York, read a paper with this title. He said that for every person obviously insane there was probably another who had, at some period of life, been affected with a less obvious form of brain disease. The psychological survey of the supposedly insane person should be similar to that employed in every-day life in sizing up the mentality of our saner fellow-men; it should inquire into his power of perception, attention, memory, reasoning power, and ability to plan, choose, execute, or will. In all cases of insanity the play of the muscles, whether in mimicry or in the coarser bodily movements, should be carefully noted. Conventionality must also be taken into account.

---

*Second Day—Wednesday, June 28th.*

**Traumatic Neurasthenia.**—Dr. John D. McGill, of Jersey City, read an essay on this subject. He said that traumatic neurasthenia was, correctly speaking, a traumatic functional neurosis, depending for its causation upon, first, a prior existing neurotic diathesis as a predisposing cause, and second, upon shock or injury, or both, as an exciting cause. From a large experience he was convinced that in the great majority of all cases of traumatic neurasthenia a potent predisposing factor was the condition of the nervous system. A nervous temperament, apparently due to heredity alone, was frequently observed. Hitherto neuropathology had been largely speculative, but it gave promise of great results in the near future. The nervous influences following concussion of the spine, the essayist said, had been noted and commented upon by surgeons a century ago. In 1818 Sir Benjamin Brodie had recognized forms of hysteria following injury. In 1856 Erichsen had first treated of the nervous disorders that follow railway injuries, and for a time his views had been practically unchallenged. In 1875 the same author had issued a book on "Concussion of the Spine," which had aroused a vast deal of discussion. In the light of our present knowledge of neurology, his views were unsatisfactory and, in the main, incorrect. From a consideration of the extensive literature of the subject it seemed that the majority of writers agreed, first, that no nervous disease could be attributed directly to trauma, and, second, that nervous disease might follow injury or shock, either separately or more commonly associated with it. Traumatic neurasthenia, then, might be defined as a disorder of the nervous system of a functional character, attended with loss of vitality, weakness, and exhaustion of the nerve centres, the exciting cause being trauma or shock. Traumatic neurasthenia and traumatic hysteria, although frequently associated, were not absolutely identical. The disease was rarely if ever fatal *per se*, and hence its pathology was but little known. From a clinical study of the disease, it was fair to assume that the morbid anatomy of the disease was to be looked for in nutritive changes in the cell nucleus, due to vitiation of the cell protoplasm.

Etiology: The causes of traumatic neurasthenia were many and various. The character of the accident and the nature of the injury received had a decided influence on the development of the disease. Railway accidents were especially prone to be followed by this disorder, probably largely because of the suddenness of the accident and the profound impression made upon the nervous system. According to the prominence of psychical or physical shock would the symptomatology incline toward traumatic hysteria or traumatic neurasthenia. Ordinarily, the existing trauma was comparatively trifling; on the other hand, the nerve shock was great. Persons asleep at the time of the occurrence of the accident would escape much of the shock.

Symptoms: The first symptoms were loss of sleep, aching of the back and limbs, and an unusual irritability of temper. Later on the person often became moody and shunned his friends. The existence of mental exhaustion was particularly characteristic, the individual being unable to keep his attention long on any subject except upon himself and his miseries. The absence of objective symptoms made this field a particularly fertile one for lawsuits. In uncomplicated cases of traumatic neurasthenia the tendency was toward recovery.

Dr. J. Leonard Corning complimented the essayist on his elucidation of this difficult subject, and particularly on his differentiation of psychical and physical shock. Many of these persons would recover rapidly unless a lawsuit was brought; in others there was a true physical basis. In the latter class recovery would usually take place in one or two years.

Dr. William M. Leszynsky, of New York, said that the author had done a good service in showing clearly that there really were such cases as traumatic neurasthenia in existence. The majority of general practitioners were inclined to believe that these cases were all simulated. He had seen a number of cases in which men who had been previously in perfect health had developed all the symptoms enumerated in the paper. Many of these patients continued ill even after having received substantial damages at law. The prognosis was always uncertain, and could not be said to depend upon the amount of damages or the case being thrown out of court. At times even expert neurologists would be deceived in their estimate of these cases.

Dr. S. Lamson, of Jersey City, said that the essay was an exceedingly practical one, coming as it did from a surgeon who had had an extensive experience in railway surgery. It had seemed to him that the specialist in such cases as these was often prone to refine matters too much. Any practitioner was liable to be called into court to testify in these cases as a witness to the fact.

**The Progress, Problems, and Prospects in Medicine.**—Dr. John Bruyere, of Trenton, presented in this essay a number of suggestive queries regarding tuberculosis, such as the following: Why did all cold-blooded animals present immunity, while warm-blooded animals were susceptible to tuberculosis? Why was it that the Indian who lived an out-door life in the best possible climate was so much more prone to tuberculosis than the white race? Was the pneumonia resulting from tuberculosis due to the tubercle bacillus and its toxin, or to secondary infection with other germs? Why was it that free incisions into tuberculous tissue set up a healthy action in the parts? Was the bacillus of bovine tuberculosis identical with that which gave rise to tuberculosis in the human subject? Was consumption of vegetable origin, and was it due to a parasite?

**Cyclic Vomiting.**—Dr. Alexander Marcy, of Riverton, presented a communication with this title. He said that scarcely any reference was made in the

text-books to this important but rather rare affection in children. He had happened to meet with three cases among children during the past five years. One of them had been mild and the other two very severe. The first noticeable symptom was loss of appetite and usually a refusal to eat the evening meal. The tongue was slightly coated and the breath rather heavy. During the night, usually between twelve and two o'clock, the child would awaken, complain of feeling sick, and then vomit. The vomited matter consisted of the food taken the day before, accompanied with considerable mucus. This would be followed by an elevation of temperature and a profuse secretion of urine. After the stomach had been emptied of its contents the vomitus would consist of mucus, and later on would contain some blood. There were severe retching and intense thirst, and anything and everything taken into the stomach was rejected. There was a peculiar odor to the breath and the vomited matter, from which alone Dr. Marcy said he would be willing to make the diagnosis of cyclic vomiting. In a few hours the child became very restless and exhibited a curious intolerance to all bed-clothing. After continuing for perhaps forty-eight hours, with a slowly falling temperature, there would be every evidence of extreme exhaustion. Again, the temperature would rise perhaps to 105° F., and in a day or two more the physician would probably give up all hope of the patient's recovery; but it would be noticed about this time that the intervals between the vomiting were longer. The child would next become drowsy, and after a deep sleep the crisis would be passed, and the patient would make a remarkably rapid convalescence. This affection seemed to be associated with a general derangement of nutrition associated more or less definitely with deficient excretion of uric acid. Holt had suggested that it was due to an accumulation of some toxin in the system. This form of vomiting often occurred in children in whom the diet had been regulated with special care. It might occur at any age, but was chiefly observed in early infancy and childhood. The speaker said that he was convinced that it was due to influences beyond the stomach, but just what these influences were he was unable to say. He believed these cases were examples of auto-intoxication due to ptomain poisoning, the ptomains being formed in the intestinal canal and absorbed from there. A study of the urine before the attack showed that it was always scanty and highly acid, and contained an increased quantity of indican. Subsequently the quantity of indican diminished, and the quantity of acetone increased. The pathological examination of a fatal case had shown marked inflammatory change in the mucosa, particularly at the pylorus and in the duodenum and ileum. The gall bladder was distended with bile. The spleen, pancreas, and kidneys were unaltered. Microscopical examination of the mucosa of the stomach and intestine showed almost complete necrosis, with fatty infiltration of the liver and slight parenchymatous change in the spleen and kidneys. It was evident, therefore, that there had been a very severe grade of gastro-intestinal inflammation. Shortly before death, in another fatal case, the urine had contained many renal casts and some blood. The disease was self-limited, and tended ordinarily toward recovery. Treatment was absolutely useless; even rectal alimentation was of doubtful utility, but should be employed. Hypodermic injections of morphine and atropine relieved pain and exerted some control over the vomiting. Digitalis, strychnine, and saline solution sustained the heart, and seemed to be indicated. They should be employed quite early in the disease.

Dr. Henry Chavanne, of Salem, referred briefly to four cases which he had treated successfully by administering exceedingly small doses of codeine, aconite, and veratrum viride. Half a grain of codeine, one one-hundredth of a grain of aconite, and a small quantity of veratrum had been dissolved in a glass of water, and the patients given doses of half to one teaspoonful of this mixture at short intervals until they became drowsy. After a prolonged sleep, recovery rapidly ensued. The pathological lesions described in the paper were probably nothing more than the effect on the tissues produced by continued vomiting.

Dr. Charles P. Noble, of Philadelphia, said that his experience, as an abdominal surgeon, with cases of post-operative intestinal toxæmia would lead him to suggest the advisability, in these cases of cyclic vomiting, of frequently washing out the intestinal canal. Such treatment would sustain the heart at the same time that it favored elimination.

Dr. Marcy said that the very simplicity of the treatment employed by Dr. Chavanne seemed to him the best evidence of its inutility. The very moment that the toxin had been eliminated the child would naturally go to sleep, and might not awaken for twelve or even twenty-four hours. When the first symptoms appeared the toxin had already got into the blood. He had tried irrigation of the bowel with saline solution, but it had proved as futile as the many other methods of treatment that he had employed. He believed that the only way to get the toxin out of the system was by transfusion, and he proposed to try this plan in the next case coming to him for treatment.

Dr. Philhower indorsed the treatment employed by Dr. Chavanne, and expressed the belief that it had saved the lives of those children.

**Two Cæsarean Sections on the Same Patient.**—Dr. John C. McCoy, of Paterson, reported this interesting case. The first labor had been long and difficult, requiring embryotomy, and resulting in a complete laceration of the perineum into the rectum. About one year later Cæsarean section had been performed, the family insisting that every effort should be made to save the life of the child, and that, if possible, none of the genital organs should be sacrificed. The woman had recovered rapidly from the operation and had left the hospital on the twenty-first day. Six months later there had been a slight discharge from the lower end of the abdominal wound, and examination had shown the presence of an abdominal fistula leading into the cavity of the uterus. Seven months later there had been a bloody discharge from this sinus, which had been coincident with the reappearance of menstruation. This discharge had recurred with each menstruation, had had a brighter color than the blood issuing from the vagina, and had appeared about one day earlier than the latter. Operation had been advised, but declined. A few months after this she had again become pregnant. At the supposed termination of gestation, there being no signs of labor, the old incision had been opened. There were extensive adhesions between the uterus and the parietal peritoneum, making this second laparotomy practically extraperitoneal. The cicatricial tissue about the sinus was dissected out, and the tissues were then united by suture. Both ovaries and tubes were removed at this operation, after a child, weighing seven and three-quarters pounds with the placenta, had been delivered. The whole operation had been completed within an hour. The mother had recovered nicely from the operation, but, on going home, both she and the child had contracted diphtheria. The child had died, and the mother had made a tedious convalescence. The child delivered by the first Cæsarean section was still alive. The Cæsarean section in this case had proved to be much less severe than the embryotomy.

Dr. Stillwell, in discussing this paper, referred to a young dwarf, the internal conjugate diameter of

whose pelvis measured only one and three-quarters inches. She had been three months pregnant when first seen by him. Dr. E. B. Cragin, of New York, had performed Cæsarean section on her at the proper time, and had removed the ovaries and tubes because of the small diameter of the pelvis and the impossibility, in such a pelvis, of securing proper drainage. The child weighed at birth four pounds nine ounces, and was alive and well at the present time.

Dr. P. A. Harris, of Paterson, said that when, in a young girl of sixteen years, the cervix had fully dilated and the membranes had broken, and still the head of the fœtus could not be made to engage, if the child was living Cæsarean section was indicated, whether the pelvis measured two and one-quarter or three and one-half inches. But in the same girl, four years later, the conditions might be so changed as to make such an operation wholly unnecessary; hence the necessity for testing each case during labor and also for leaving the ovaries and tubes in such young girls.

Dr. Charles P. Noble, of Philadelphia, said that he had been concerned in two cases in which Cæsarean section had been performed the second time on the same patient. He did not see why a woman should be denied the privileges of maternity because unable to have a baby in the natural way. It was a thoroughly settled fact, that Cæsarean section, if done under favorable circumstances and by a competent operator, was attended by a mortality of not more than two or three per cent. Of course, if the woman elected to have further conception prevented, he would operate in accordance with that wish. For this purpose, the best method was to remove only the Fallopian tubes. He would not elect to do the Porro operation unless there was a tumor present or the woman had become infected or was likely to; the Sänger operation seemed to him preferable. The second, third, or fourth Cæsarean section on the same patient was not more fatal than the first one.

**Progress in Surgery.**—Dr. Dowling Benjamin, of Camden, presented this report. He said that there had been no great discovery in surgery since that of the Roentgen rays. Progress during the past few years had consisted largely in improvements in technique.

Sterilization of Catgut and Hands: The method of sterilizing catgut which Dr. Benjamin recommended as the best consisted in soaking the catgut for twenty-four hours in oil of gaultheria or oil of juniper, and then preserving it in strong alcohol. Regarding sterilization of the surgeon's hands, he said that out of one hundred and twenty-five cases one observer had failed to secure sterilization with formaldehyde in seventy-five cases, but another investigator had reported success with this method in seventy-five per cent. of his cases.

Murphy Button: This device, the speaker said, still held its own; he looked upon it as the quickest and safest method yet discovered for uniting the intestine. The progress of the button could be noted with the aid of the *x*-rays.

Foreign Bodies in the Œsophagus: The ingenious method devised by Dr. E. J. Ill, of Newark, of locating foreign bodies in the œsophagus and stomach by means of a wax-coated bougie constituted a distinct advance in the surgery of this region. Dr. H. A. Kelly had lately made use of such a coated bougie for detecting calculi in the ureter.

**Progress in Diseases of the Nose and Throat.**—Dr. T. W. Corwin presented this report. He said that the Asch operation for deviated nasal septum seemed to have received the most favor, and it had the advantage of being applicable to the most formidable deformities. About its only disadvantage was the necessity for using general anæsthesia.

Nasal Diphtheria: Dr. Corwin said that examination with a nasal speculum in cases of nasal diphtheria would reveal adherent patches of membrane of such strongly characteristic appearance that the diagnosis of Klebs-Loeffler diphtheria in the nose could be easily made by this alone—at any rate, in each case in which he had made the diagnosis by this method it had been confirmed by the bacteriological examination. For the successful treatment of adenoids, the finger and the forceps curette were required, together with thorough and patient manipulation under full anæsthesia.

Hypertrophied Tonsils: Cases of slight hypertrophy of the tonsils were best treated by galvano-puncture; for the larger ones, Bosworth's snare was very useful, but required the injection of cocaine into the tonsil.

Epistaxis: For the control of epistaxis, the application of oil on cotton had been highly recommended. Suprarenal extract was useful in many vascular conditions, both acute and chronic, and the system did not seem to become easily habituated to its use.

**Progress in Diseases of the Eye and Ear.**—Dr. Frank C. Ard, of Plainfield, presented this report. He said that the treatment of scleritis by subconjunctival injections of a solution of mercury of strength of 1 : 1,500 had been recommended as a valuable method. A recent report from Paris had stated that protargol soluble bougies were better in lacrymal affections than nitrate of silver. Two cases of pseudomembranous conjunctivitis due to staphylococci and streptococci had been reported as having been successfully treated with Marmorek's serum. Protargol had been found decidedly inferior to silver nitrate for the treatment of gonorrhœal, granular, and catarrhal ophthalmias. Deutschmann had now done his operation for detachment of the retina one hundred and one times, and had cured twenty-eight and improved thirty-four cases. In the original operation, first published in 1895, the eyeball was opened subconjunctivally and the vitreous and retina were divided; in his present operation he also made a counter-opening. Atrophy of the optic nerve had been reported as following the administration of certain drugs. A useful method of dealing with carious bone in the tympanic cavity had been reported. It consisted in the application of a four-per-cent. solution of hydrochloric acid on cotton to the visible dead bone. It was allowed to remain there until the following day. The acid usually decalcified the bone, producing a result similar to that of curetting, while at the same time it acted as an antiseptic. Altogether seventeen hundred and fifty mastoid operations had been reported, with a mortality of about fifteen per cent. There had been a decided advance in the treatment of the cerebral complications of ear disease, particularly sinus thrombosis. Dr. Fred. Whiting, who had had an exceptionally large experience with this affection, recognized three stages, viz.: (1) One in which there was a more or less complete thrombosis, associated with moderate pyrexia, but in which the thrombus had not yet become disintegrated; (2) a stage in which the thrombus was disintegrating, characterized by sharp rigors and other evidence of sepsis; and (3) a stage in which, after complete disintegration of the thrombus, there was septic absorption. According to this authority, there should be no fatalities in the first stage, and even in the third stage there was still hope from appropriate operative treatment.

**Progress in Bacteriology.**—Dr. E. C. Baldwin, in this report, considered the diagnosis of tuberculosis, diphtheria, typhoid fever, and hydrophobia from the standpoint of the bacteriologist, and dwelt upon our knowledge of bird malaria and the part played by mosquitoes in disseminating malarial infection.

**Pleuritic Adhesions and Diseases of the Chest.**—Dr. D. H. Goodwillie, of New York, exhibited two beautifully prepared models made from the dissection

of the body of a child. The first model showed numerous pleuro-plastic adhesions, particularly to the pericardium. In the second model the lung was thrown up so as to expose the adhesions between the pleura and diaphragm, and teach in a graphic manner the influence that such adhesions must necessarily exert upon the heart. If a large surface of the pleura was affected, Dr. Goodwillie said, the respiration would be seriously disturbed, but the physician should be able to recognize these conditions of the pleura long before such an advanced stage had been reached. Physicians were too apt to cease their visits, in a case of pleurisy, just so soon as the pain had been relieved. The models were presented with the object of calling attention to the fact that there might be extensive adhesions of the pleura to the pericardium as well as to the diaphragm, and also to emphasize the importance of recognizing and appropriately treating these and similar conditions which, by interfering with normal respiration, seriously impaired the vitality of the individual.

**Circumcision—Its Moral and Physical Necessities and Advantages.**—Dr. A. W. Taylor, of Beverly, read this essay. He said that the operation of circumcision was thirty-seven hundred and ninety-seven years old, the first operation having been done on a person ninety-nine years old, and the next on his son of nineteen. The operation had evidently had its foundation in sound physiological reasons. There could be no doubt that the original divine decree had been intended as a sanitary precaution. Circumcision was the oldest of all surgical operations. Not all cases of congenital or inflammatory adhesions of the prepuce to the glans were continued to adult life, but circumcision and the removal of these adhesions contributed largely to the comfort of the individual. It was not necessary that the constriction should be complete or the prepuce narrow and long to give rise to severe nervous symptoms. The organ was exceedingly sensitive to mental or local irritation. Phimosis was responsible for a long series of formidable symptoms. The speaker was of the opinion that not infrequently marital unhappiness would be better relieved by circumcising the husband than by suing for divorce, and that a man before marrying should be examined with this operation in view should it be indicated.

**Report of the Committee on Abuse of Medical Charity.**—Dr. T. Y. Sutphen, of Newark, the chairman, presented the report. It stated that medical charity was rendered in five counties of the State, *i.e.*, Essex, Hudson, Camden, Passaic, and Mercer, and that in these over sixty thousand new patients were recorded annually. Very few were required to pay anything. In none of these counties was there an efficient system of investigation to determine the necessity for such aid. In the opinion of the committee there seemed to be no way of correcting this evil except through legislation, and the education of the public opinion through the influence of the medical profession. The committee recommended that the society should present to the legislature of New Jersey a bill which would make it unlawful to treat a patient at any dispensary a second time unless such person had a certificate signed by a person duly authorized by the district society of the county.

The report elicited a lively discussion, but while all admitted the reality of this evil, the opinion prevailed that it was inexpedient to ask for legislation at present. The committee was continued, and asked to present at the next annual meeting suggestions regarding the form which the proposed legislation should take.

**Case of Tumor of the Brain Affecting the Optic Chiasm.**—Dr. William J. Atkinson, of Paterson, reported a case of this kind. The patient had had an exceptionally good family history. There had been marked polyuria and great thirst for four years previous to the patient's coming under his observation. Examination had shown partial ptosis of the right lid and of the right internus muscle. The edges of the optic disc were somewhat blurred, and there was a marked difference in the relative size of the vessels, the veins being very much larger than the arteries. There was double vision on carrying the object to the right or above the horizontal plane. There was paresis of the third or motor oculi nerve. The urine was pale, of low specific gravity, was free from sugar, and contained a trace of albumin. The patient voided six and one-half pints of urine in twenty-four hours. The case was reported with great fulness of detail, including the autopsy record. The chief point of interest was the persistent polyuria associated with a lesion at the base of the brain.

Dr. W. M. Leszynsky said that when he had seen the patient there had been no irritative symptoms of cerebral tumor or signs of interference with the motor tract. Without examination of the visual fields no localization would have been possible.

Dr. Judson Daland, of Philadelphia, said that this case was of considerable value as apparently demonstrating the association of round-cell sarcoma of this region with polyuria. He reported a case, occurring in a boy of ten years, in which the marked polyuria had apparently resulted from cerebral disease.

**Acute Otitis Media.**—Dr. Norton L. Wilson, of Elizabeth, read this paper. He said that there existed a difference of opinion as to the best treatment to be pursued. The catarrhal form was more frequent than the purulent, and the latter class would be still less frequent if the catarrhal cases were properly treated at the beginning. The varieties of otitis media resulting from influenza were pointed out. He had known a case of acute otitis media, of so violent a type as to rupture the membrana tympani, to run its course without pain. Such cases were very rare unless they were due to tuberculosis. Particular attention should be given to inspection of the parts lying close to the short process of the malleus whenever pain in the ear was complained of. Such inspection would reveal the fact that this portion of the membrane was distinctly congested and presented a deep, dull red color, showing a high degree of venous engorgement of the underlying structure. This hyperæmia did not extend below the posterior fold. It was in these early stages that the family physician saw these cases, and he should adopt measures to control the inflammation promptly. His own practice was to put the patient to bed and administer calomel in small doses until copious evacuations of the bowels were obtained. At the same time, he applied leeches in front of the tragus and endeavored to relieve the pain by irrigating the ear with hot water through a return-tube fitting closely into the meatus. In this way the irrigation could be carried on without removing the instrument from the ear. Many otologists objected to this method on the ground that moist heat favored suppuration, but his own experience had convinced him that the venous stasis was thereby relieved, instead of increased as the others maintained. In his practice he had been able to dispense with the use of "ear drops" of any kind since using the continuous hot-water irrigations. In these cases he never neglected the toilet of the nose. If the nasal mucous membrane was much swollen, he dropped into the nose a watery solution of the extract of the suprarenal gland. A soothing application was a solution of menthol dissolved in one of the coal-tar oils. He sometimes gave acetanilid, but was loath to give opiates, particularly until after the bowel had been freely evacuated. The above treatment should be carried out until the indications were present for

puncture of the drum membrane. By this conservative method he was sure that rupture of the drum membrane had been frequently averted, and hence he did not favor the routine practice of early resort to puncture of the membrane. If after a delay of twenty-four or thirty-six hours the pain was intense and increasing, and the drum membrane was bulging, he did not hesitate to puncture it. Before doing so it was his custom to endeavor to anæsthetize the membrane by instilling a warm six-per-cent. solution of cocaine. In incising the membrane a cataract knife was more useful than the ordinary spear-shaped knife specially made for this purpose. An effort should be made to divide the swollen tissues in the superior and middle portions of the ear. The hemorrhage was encouraged by irrigation with warm sterilized water, provided the discharge was purulent. As a rule, the serious cases terminated favorably within a week. The suppurative cases usually ran for two or three weeks.

Dr. Frank C. Ard favored the use of a ten or fifteen per cent. solution of cocaine prior to puncture of the membrane, allowing about ten minutes to elapse before making the incision. He also was a thorough believer in the use of the hot douche.

Dr. C. Kenneck said that in almost every instance he had succeeded in relieving the earache by instilling about ten drops of a strong solution of atropine (four grains to the ounce) and repeating it within an hour. He also had great faith in applying to the ear a hot baked potato in a stocking.

Dr. D. H. Goodwillie was of the opinion that very many cases of otitis originated in nasal disease; hence his practice was to give attention to relieving the nasal stenosis and cleansing the passages.

Dr. Judson Daland said that in certain cases of typhoid fever, in which there was a secondary rise of temperature, it would be found that there was an acute suppurative otitis media. In some instances the delirium and the so-called insanity were to be attributed to the same cause.

Dr. Wilson, in closing, said that if a six-per-cent. solution of cocaine would not anæsthetize the drumhead, a fifteen-per-cent. solution would not, and this was because the epithelium in such cases was intact. In his experience, atropine had more often failed than succeeded.

**Does Medicine Cure?**—Dr. Henry Chavanne, of Salem, read a humorous and suggestive paper with this title. He stated that early in his professional career he had been quite scientific. At one time, when remonstrating with a druggist for counter-prescribing, the latter had replied: "Doctor, you are too scientific. What people want is relief, and they want it right away. When the sequelæ come, then they will come to you." Since that time, the speaker said, he had been more enthusiastic over the use of medicine.

*Third Day—Thursday, June 29th.*

**Nephrectomy and Resection of the Ureter.**—Dr. E. J. Ill, of Newark, reported a case of tuberculosis of the kidney in which he had done this operation. After having extirpated the kidney through an incision in the loin and ligated the ureter in continuity, he had made a second incision through the linea semilunaris just above the pubes, pushed the peritoneum back until the iliac vessels had been exposed, dissected out the ureter, and completed its removal through an incision in the posterior wall of the vagina.

**Officers Elected.**—The remainder of the session was devoted to the transaction of routine business. The following officers were elected: *President*, Dr. Luther M. Halsey, of Williamstown; *First Vice-President*, Dr. William Pierson, of Orange; *Second Vice-President*, Dr. John D. McGill, of Jersey City; *Third Vice-President*, Dr. E. L. B. Godfrey, of Camden; *Corresponding Secretary*, Dr. E. W. Hedges, of Plainfield; *Recording Secretary*, Dr. W. J. Chandler, of South Orange; *Treasurer*, Dr. Archibald Mercer, of Newark.

**Place of Meeting.**—The next meeting will be held at Atlantic City, June 4, 1900.

## Surgical Suggestions.

**To Prevent Surgical Shock.** — If you expect to get much shock from an operation, remember that here again prevention is better than cure. Use a little morphine before operating to quiet the nervous system; keep the patient very warm before and during the operation, as well as after operation. Small doses of strychnine before the operation are also indicated.—*North Carolina Medical Journal*, March.

**A Method for the Sterilization of Urethral Instruments.**— Dr. Gerald Dalton describes in *The Lancet* (February 18, 1899) a simple apparatus for sterilizing urethral instruments. It is an oblong metal box, eighteen inches long, four inches wide, and four inches in depth, provided with two sliding, open wire-work trays, upon which the instruments are laid, while underneath is a layer of lint, stretched on another wire tray, the tray to be just off the floor of box. On the lint is sprinkled a thin layer of powdered paraform or trioxymethylene, which slowly gives off vapor, effectually sterilizing in twenty-four hours the instruments in the upper two trays (Guyon). The box is closed by a metal cap fitting closely. Formol may be used instead of its derivative, but is liable to injure soft instruments. Instruments may be left in the box for any length of time without harm. It is as well to immerse the instruments for a few minutes in a boric-acid solution just before use, since, if they are taken directly from the sterilizer and passed into the urethra, they may cause some little stinging sensation. All instruments should be thoroughly washed in soap and water and dried before being placed in the sterilizing box, and the box itself should be kept at a temperature not below 56° F.

**Surgical Hints.**—(1) Whenever you suspect the presence of severe internal injuries, never allow the patient to get up and go about very soon. It is always of great importance to secure as long a period of rest and quiet as possible.

(2) In bony ankylosis there is no pain in voluntary efforts of motion; in fibrous ankylosis there is. In the first, if the physician tries passive motion, the pain is only where his fingers compress the part; in the latter there is pain all over the joint.

(3) In any of the forms of chronic superficial inflammation of the tongue it is unwise to use caustics. These agents commonly increase the irritation, such cases showing marked tendencies toward malignant development, and must always be carefully watched.

(4) Never treat a severe burn on the flexor part of the joint without applying an appropriate splint to prevent as much as possible the occurrence of contraction. The need of skin grafting is especially great in all burns where the result of contraction would be deformity or disability.

(5) In dislocations at the shoulder-joint, a rapid test consists in applying a straight ruler to the acromion process of the scapula and the external condyle of the humerus. If it touches both joints at the same time there is dislocation, for normally the deltoid prominence prevents this.

(6) In young people complaining of pains and swell-

ing in the neighborhood of a joint, especially about the long bones, examine very carefully to see whether the trouble is in the joint. If it affects the bone itself, the chances are in favor of malignant rather than arthritic trouble. If malignant the development is usually rapid. There are usually glandular enlargements. The tumor is uneven in density, the superficial veins increase fast, and the pain is more or less constant and of a shooting nature.

(7) To remove blood from the hands use soap only after washing in plain water.

(8) Sweeping and dusting should not be done just before an operation. Cover possible dust collections with wet sheets.

(9) In amputations loose muscles retract more than those attached to bone. Hence sever the loose muscles first, so that the ends may be of equal length.

(10) If the wound is clean leave it alone; the best surgeons apply but one dressing.

(11) Wash out the nasal passages before giving ether to subjects of catarrh.

(12) Scalp wounds, if large, should be stitched, but stitches should be removed early.

(13) In felon find out if the bone is attacked. Amputation of the terminal phalanx is best delayed until the septic process is overcome.

(14) In frost bite do not amputate early. Use thorough asepsis, and maintain the patient's strength.—*International Journal of Surgery.*

**Vaginal Cæsarean Section.**—The *Medical Review* (March 25th) credits Dührssen, of Berlin, with formulating the following indications for the operation: (1) Abnormalities of the cervix and lower uterine segment, which render dilatation impossible or difficult (carcinoma, rigidity, stenosis, sacculation). (2) A dangerous condition of the mother, that renders speedy delivery necessary. (3) Dangerous conditions that will lead to speedy death.

**The Gibney Treatment of Sprained Ankle.**—Dr. J. Howe Adams (*The Railway Surgeon*, January 10, 1899) describes the method as follows: Ordinary adhesive plaster is cut into strips one-half inch wide and in two lengths, about twelve and eighteen inches long. Taking up the foot as soon as the patient is seen and the diagnosis is made, one of the longer strips is placed around the ankle, parallel to the sole of the foot, beginning in front of the big toe, carrying the strip around the ankle just above the contour of the sole, and bringing the end back across the top of the foot to about the point where the strip began. It is well to place, overlapping this initial strip, a parallel piece. In placing these strips, care should be taken to draw them as tightly as possible, so that the bandage will fit snugly when finished. Having applied these strips, another strip should be placed at right angles to them, which makes it run parallel to the back of the leg. One of the shorter strips should be selected for this purpose. Beginning well behind and above the ankle, this strip should be carried down around the sole of the foot and brought up on the other side of the leg, making, as it were, a stirrup for the foot. The same precaution of applying the strip as closely as possible should be observed. Now the strips should be applied alternately, first one around the ankle parallel to the sole, then one parallel to the back of the leg, each one overlapping the one previously applied, running in the same direction, to some extent. This procedure should be kept up until the entire foot is enclosed in a boot of adhesive plaster, having the appearance of a shoe in which part of the heel has been cut away. This dressing, properly applied, has a very neat appearance; over it can now be placed an ordinary roller bandage, which will serve to help the adhesive plaster to "take hold." The patient should now be cautioned to be careful for a day or two, when he can begin to move around rather freely. This dressing can be kept on until the pain and swelling have subsided, when it can be removed, and no especial further treatment is indicated. If the dressing becomes loose, it can be re-enforced by additional strips placed over the loose ones.

**Epilepsy.**—Operate in: (1) Focal or partial epilepsy (Jacksonian) when the convulsions are limited to a particular group; (2) in epilepsy, general or partial, when the condition is followed, or was apparently caused by, traumatic depression; (3) in many cases in which partial epilepsy has followed a head injury, even if there are no external indications, but in each signal symptoms indicate the brain area affected.—McCosh.

---

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

MORE ABOUT PREVENTIVE INOCULATION—EPIDEMIOLOGICAL SOCIETY—SEWER VENTILATORS—MEETING AT COLLEGE OF SURGEONS—ANTI-MALARIAL INOCULATION OF TROOPS—HOSPITAL SUNDAY FUND—CANCER SOCIETY—DEATHS OF SIR WILLIAM FLOWER AND SIR ALEXANDER ARMSTRONG.

London, July 7, 1899.

I said so much in my last letter on Mr. Haffkine's account of his preventive inoculations, as described to the Royal Society, that I had not space to dwell upon the short discussion which followed. However, it is not too late to report some of the remarks which were made and which seem of particular interest.

Professor Wright, being on the plague commission, could not anticipate their report; he acknowledged Mr. Haffkine's experiments and results to be brilliant, but he felt it far more important to ascertain whether inoculations would be applicable to other infectious diseases than whether a few lives had been saved. But no doubt Mr. Haffkine had done much good, and if any harm had ever been done the good greatly overbalanced it.

Surgeon-General Harvey, director-general of the Indian medical service, pointed out the great difference between laboratory research at home and a campaign against an epidemic in India. In spite of all, the results were remarkable, and he had investigated some of the outbreaks himself and testified to Mr. Haffkine's accuracy. He could find no source of error, and the difference in favor of the inoculated was about ninety per cent. At Habli about eighty thousand inoculations were made, and only about a dozen abscesses occurred. He had himself been inoculated. The effects were certainly unpleasant, but he could carry on his work. The fever passed in a day or two, but the arm remained painful for a week.

Prof. W. J. Simpson had been associated with Mr. Haffkine in his earlier work on cholera, and testified to his great caution and unbiassed character. So great was it that it often looked as if Mr. Haffkine was the greatest antagonist of the result, criticising every fact from the most adverse point of view. Wherever inoculations were carried out for plague or cholera when they prevailed the incidence was always less on the inoculated.

Lord Lister (president) said if any one before that meeting had doubts, those doubts must be removed by the address. As to further progress, of course, that

was as possible in this as in other cases, and some requirements might perhaps be necessary, in which case he was convinced that the best man in the world to attend to them was Mr. Haffkine himself.

The annual dinner of the Epidemiological Society was notable for an important speech made by Mr. Haffkine in responding to the toast of the visitors, which was proposed by Dr. Payne, who said he had no doubt of the efficacy and great benefit of inoculation against plague. The speech was quite out of the usual lines of such performances. Mr. Haffkine expressed his pleasure at seeing London epidemiologists collected into an organized body of scientific investigators, and made a strong plea for a general organization of studies. He said scientific problems necessitate the maintenance of not less strict and combined a service of trained workers than a military organization or any complicated enterprise. The scientist from whom useful teaching is expected must be able to know every collaborator with whom he is sharing part of the work; must be aware of his special aptitudes and abilities; must appreciate his observations and reports; must, as it were, look through the instruments and eyes of his staff, listen through their ears, so as to reckon at any moment on their loyal co-operation in the common task of research. It is only by transforming a scientific school into one collective investigator that important knowledge can be gathered and the study of such calamities as epidemics can yield useful truth for the benefit of mankind.

Mr. Lithiby, assistant secretary of the local government board, also spoke. He said epidemiologists should not lose heart because their work is not at once taken advantage of by the legislature, as an act of Parliament is the resultant of many complex forces. They have the consolation that what they think today the local government board will not improbably think to-morrow.

Dr. Church, president of the Royal College of Physicians, gave the toast of the Epidemiological Society, the oldest of our societies dealing with public-health questions, founded in 1850, the first president being Dr. Benjamin Guy Babington, who has been followed by a long line of distinguished successors. Dr. Church gave an interesting epitome of the society's history, and said it differed from others in its cosmopolitan character, having correspondents in all parts of the world and dealing with the behavior of diseases in communities rather than with clinical and pathological studies or with administrative questions. He added that whatever progress might be made in bacteriology the need for checking the results of laboratory experiments by epidemiological observations must still remain.

Sir Charles A. Cameron, C.B., M.D., lately brought before the Royal Institute of Architects a new method of ventilating sewers which he has successfully tried in Dublin. In the course of his remarks he pointed out that in Bristol the sewers are not ventilated at all, but discharge their contents into a tidal river in which the tide prevents the outflow for a considerable part of the day. Yet Bristol enjoys remarkable immunity from typhoid fever, and the health of the men engaged to cleanse the sewers does not suffer. Nevertheless, Sir C. A. Cameron is in favor of ventilating street sewers, though he objects to the narrow, confined openings which are so common. He therefore determined to rely on the property of diffusion of gases through porous materials. He uses cylinders composed of porcelain clay two parts and sulphate of lime one part; they are made eighteen inches in height and six in diameter, and four or six are put in the crown of the sewer in a chamber like that of ordinary ventilators. The cylinders allow gas to pass through them, but filter off microbes. The pressure in the sewer and outside is therefore kept equal. Rain is carried from the chamber through a small siphon. The "fresh-air inlets" of house drains are often foul-air outlets. Mica valves and other appliances have all heretofore failed. A porous plate after the same suggestion would no doubt be better. Sir C. A. Cameron's invention has been efficacious in Dublin. The diffusing ventilators have been examined, after being two years in use, and found quite clean.

The meeting at the College of Surgeons came off on Wednesday. It was not so fully attended as when there was more agitation; still a respectable audience was present. Sir W. MacCormac presided, and hoped no contentious questions would be raised, but that the proceedings be confined to the proposal to obtain power to elect honorary fellows and members, which was not contentious. Such a hope was, of course, vain. While thousands of members are deprived of their rights by the few hundred fellows, they will be foolish not to oppose any new charter which does not restore some at least of those rights.

Mr. Joseph Smith, president of the Society of Members, accordingly moved a resolution that no charter should be obtained without a provision for the representation of members on the council. This was eventually carried by 40 against 8.

A second resolution was proposed requesting the council to postpone action in the matter until they had considered a memorial now in course of signature. This, after a somewhat sharp discussion and sarcastic references to the council, was carried by 38 to 1. That single dissentient represents a good deal of obstruction, and the reform which must sooner or later be accomplished may yet be delayed. The members should, as I said, oppose any charter that does not satisfy them. They may have to adopt very strong measures to obtain their rights.

Some of the troops proceeding to Natal have been offered the opportunity of being inoculated against malaria. A large proportion volunteered, and the operation has been performed at Aldershot. The immediate effect is headache, pains in the limbs, and febrile symptoms. The reaction lasts only twenty-four to thirty-six hours. This will be a crucial test of the process.

The hospital Sunday-fund collection has so far reached the sum of £47,000.

The newly formed Cancer Society is sending Dr. Arthur C. Duffy to your side to report on what you are doing, and especially as to the work of the Buffalo Laboratory.

About a year ago I reported the retirement of Sir William Flower, K.C.B., F.R.S., from the directorship of the Natural History Museum. This learned scientist died on Saturday. He was born at Stratford-on-Avon in 1831. After entering the profession he served in the Crimean War as assistant surgeon, receiving the medal with four clasps. Afterward he was elected on the surgical staff of the Middlesex Hospital. In 1862 he was appointed curator of the Hunterian Museum and professor of physiology at the Royal College of Surgeons. In 1884 he became director of the Natural History Museum, where he accomplished a great work and remodelled the classification in accordance with modern science. It has been well said that no worthier successor of Owen could have been found.

The death is also announced of Sir Alexander Armstrong, K.C.B., the arctic explorer. He was born in 1822, educated for the profession at the universities of Dublin and Edinburgh, joined the naval medical service in 1842, and served in various parts of the world. He was surgeon on H. M. S. *Investigator* during the discovery of the northwest passage by McClure in 1853–54. His well-known book on this expedition appeared in 1857.

## FRACTURE OF THE PATELLA.

To the Editor of the Medical Record.

Sir: In your issue of June 24th, I read an interesting leader on "Fracture of the Patella." There is a first and essential difference to be made between simple subcutaneous fracture and fracture complicated with wounds and opening of the joint, which circumstances change at once the whole aspect of a case. I am much surprised to find no mention made of a most effective method of treatment, viz., by massage, which certainly is not known and practised as it deserves to be.

F. Semeleder, M.D.

Cordoba, State of Vera Cruz, Mexico, July 2, 1899.

## LETTER FROM NEW ZEALAND.

(From our Special Correspondent.)

MEASLES—INCREASE OF CANCER—QUACKS.

Auckland, New Zealand, June 11, 1899.

We are suffering in this colony from an epidemic of measles, which presents some peculiarities. The eruption is in most cases much darker than that which we see in England, and in adults is often hemorrhagic. It lasts much longer—four or five days at the least, and I have frequently seen cases in which it was distinctly visible, although fading, a fortnight after its first appearance. It certainly attacks many persons twice, and the number of cases in which this occurs is very considerable. A person who has had measles when a child at home seems in no way protected against another attack here. The fever is high and the eruption very copious, but it is not a fatal disease any more than in England; in fact, if I may trust to my own recollections, there are not so many cases of serious chest complications as at home. The climate is so much milder here that lung complications are not so likely to occur. But post-nasal catarrh, involving the fauces, soft palate, and tonsils, is invariably present. Personally, in twenty-six years' practice here I have never seen a fatal case, but I dare to say that an energetic young doctor, by active treatment of a very young infant, might have to give a death certificate. And the sorrowing parents would publish an advertisement thanking Dr. —— and Nurse —— for their "devoted care and attention to the dear sufferer."

In my last letter I mentioned the rapid increase of cancer both in the colony and at home. With this increase we have the usual concomitant of an increase in cancer curers. One who has made a great name and earns a very large income treats his cases with a caustic, which he says is of vegetable origin, but which acts exactly like zinc chloride. By its action, accompanied by days and nights of frightful pain, he removes many cancerous tumors which could far more easily and quite painlessly have been removed by the knife. But there are some which the boldest operator would have hesitated to touch, and which he has treated successfully—so far. One of the thyroid gland, which had, I believe, been pronounced incurable, was quite successfully removed a few months ago. I should say that he gives some internal medicine, but also relies very much on hypnotic suggestion. There is no doubt that the latter may do much good, if only by removing the gloom and depression which every sufferer from cancer experiences. But when I saw a number of these tumors removed by this process and interviewed some of the patients, I could not help thinking that perhaps regular surgeons are to blame for not consulting the wishes of their patients more, as to the method of treatment. That the dread of the knife is most unreasonable and foolish in these days of anæsthetics and antisepsis is quite true; but if the patient chooses to submit to a week's torture by caustics and will not submit to the knife, why should we refuse to use caustics, throwing the whole responsibility on the patient? Why should we drive these people into the hands of quacks? The person I am alluding to gets from twenty to one hundred guineas ($100 to $500) for his cases, and if the patent dies, as of course some do, he can always say that he was consulted too late.

Writing of quacks, will you pardon me for hinting that if you would keep your quacks for home consumption, the Australasian colonies would be infinitely obliged to you? We grow our own article, and quite enough of it. There is no restriction here on any one, qualified or not, practising medicine, surgery, or midwifery. The only disabilities of unqualified men are: (1) that they must not call themselves physicians, surgeons, doctors of medicine, or by any other title implying that they are duly qualified practitioners; (2) that they cannot give any certificate of death, or for any purpose available in a court of law; (3) that they cannot recover any fees for their attendance or operations. But they can call themselves "professor of eclectic medicine" (by the way, what is eclectic medicine?), or homœopathists, or hydropathists, or hypnotists, or cancer specialists, or anything else they like, provided they do not profess to be qualified. One advertised himself as a non-registered medical practitioner.

I came by chance on a medical directory of the United States, and was astonished to find that in the great majority of your States, if not in all, unqualified men are not allowed to practise, and even a man qualified in another State has to get registered in the State in which he wishes to practise. It seems extraordinary that in a democratic country like yours such an infringement on liberty should be allowed. Our people would not hear of such a law. It would never reach a second reading. And I speak not only of the "benighted old country," as your orators call it, "crouching under the feet of a despot," but of all the self-governing colonies. It would be impossible to pass such a law in the Australasian colonies. Whether anything of the kind exists in Canada I do not know, but if it does we can only suppose that close proximity to the despotic democracies of the United States has enfeebled the love of freedom which reigns supreme in every Briton's heart!

Seriously, there is a very strange jealousy and dislike to the medical profession among all the working classes here. It is only in the last resort that they will apply to "a doctor," and then only when all other means have failed. Their first remedy is domestic medicine; then the advice of friends; then patent medicines; then the chemist (or drug-store, as I think you call it), and last of all the qualified practitioner. I cannot fathom the cause of this intense distrust and dislike which undoubtedly exists in the colonies. Partly, no doubt, it is a feeling of class prejudice—the dislike of the uneducated to the educated. Besides this, however, there is undoubtedly a deep-rooted distrust of the profession as a profession, and this is shown often in a very curious and offensive way. In answer to the usual question, "What is the matter with you?" the patient (invariably a man) puts on a cunning leer and replies, "Ah! that's what I want you to tell me, doctor!" Some will actually refuse to give their symptoms, and expect one to diagnose their complaint by physical signs only. To these people I have only one reply—to tell them that I do not sit there to answer conundrums, and if they have nothing more to say, they had better go at once. This brings them to their senses.

Another symptom is the frequency with which one is consulted by persons already under the care of an-

other practitioner, generally of a lodge or club doctor. Why they should elect and re-elect for years men in whom they have so little confidence is a standing puzzle. But such is Demos. All these people want, in general, is a diagnosis. They want to be satisfied as to what is really the matter with them, and this satisfaction, it appears from their account, the club doctor rarely gives them. Hence the abundance of quacks, who always give the disease a name and positively assure the patient of a cure.

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 22, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 163 | 154 |
| Typhoid fever | 30 | 8 |
| Scarlet fever | 93 | 10 |
| Measles | 203 | 13 |
| Diphtheria | 161 | 42 |
| Laryngeal diphtheria (croup) | 4 | 6 |
| Cerebro-spinal meningitis | 0 | 8 |
| Chicken-pox | 9 | 0 |
| Smallpox | 3 | 0 |

**Poisonous Pantries.**—It is very desirable that the conditions under which food may become poisonous should receive more practical consideration than they do. Dr. W. W. Stainthorpe, of England, has called attention to some glaring defects in the location of food storerooms, which are worthy of attention. In house construction the position of the pantry is too often treated as of minor importance. In some houses the space under the stairs or some equally unsuitable and inadequately lighted and ventilated place is thought good enough for the purpose. In a great number the pantry is a small offshoot from the house, the ceiling, floor, and walls often being damp, owing to faulty construction; in some of these matters are rendered worse by the water taps being placed therein without any provision being made for carrying away the droppings from the tap or overflow from vessels into which the water is run. Frequently the closet—ordinary or pail—is only a few feet from the pantry window. One of the most frequent entries in his inspection note-book is "defective yard pavement," permitting of soakage of filth into the soil underneath. Not only is the soil thus rendered a good breeding-ground for pathogenic microbes, it also supplies those conditions requisite for increased virulence.

**Gelatin as a Preventive of Hemorrhage in Surgery.**—Before every surgical operation Dr. Jaboulay (*La Sem. Méd.*, 1898, No. 56) injects into the field of operation 200 gm. of decinormal salt solution containing 5 gm. of gelatin. In this manner he was able to operate on a sarcoma of the breast and a case of goitre without the necessity of ligating any vessels or of applying clamps.

**A Woman's Work among the Moqui Indians.**—Smallpox is raging to such an extent among the Moqui Indians in Arizona that fears are expressed lest the whole tribe be swept away. It is reported that the disease has gained so firm a footing and is making such rapid headway that it seems there is strong foundation for these pessimistic views. The agency physician is Dr. Mary McKee, and she, together with Mr. Shoemaker, a farmer sent by the United States government to instruct the Indians in agriculture, have been using their utmost endeavors to stem the disease. All the known methods to attain this object Miss McKee has attempted to put into force, such as vaccination, fumigation, and destroying the effects of the sick and those who have died. As may well be believed, the task has been no light one. The Indians believe that disease proceeds from an evil spirit, and their only way of fighting against it is by means of incantations and other ceremonies. Miss McKee, however, is a woman of spirit, and by the consent of the agent of the Moqui Indians commanded the entire tribe to be assembled for vaccination. To vaccination the Indians made no objection; in fact, regarded the matter as somewhat of a joke. The fumigation gave rise to a certain amount of dissatisfaction, but the climax was reached when Miss McKee seized and committed to the flames the clothes, bedding, and household furniture of those who had died of smallpox. The relatives who hoped to inherit the property regarded this as a most high-handed procedure and protested in the most vigorous terms. Nevertheless, the plucky lady, nothing daunted, pursued the even tenor of her way, nor did she desist until two of the seven villages had undergone a thorough fumigation and cleansing and every one of the dwellers therein had been vaccinated. The other villages got wind of these proceedings, and when Dr. McKee and Mr. Shoemaker came to the third to commence operations they were met by the head chief, who refused to admit them. The chief remarked that his people were willing to take any medicine that Dr. McKee prescribed, but when it came to burning their furniture and scratching the arms of their women and children they objected most strongly. Explanations as to the benefits of vaccination, disinfection, etc., were useless, and the warning that unless she were allowed to take these measures the entire tribe would probably die fell on deaf ears. Dr. McKee was determined to have her way and to save the stubborn Indians in spite of themselves. Accordingly she induced the agent to telegraph to Washington for troops to exert a little moral suasion. Secretary Alger gave orders that a company should be immediately dispatched from Fort Wingate to protect Dr. McKee and to see that her will was carried out. The government intends that Dr. McKee shall vaccinate every Moqui if it takes all the soldiers in the country to enforce her will. We wonder what the antivaccinationists will say. This is indeed compulsory vaccination.

**The Treatment of Wounded Filipinos.**—Prof. Dean C. Worcester, of the Philippine Commission, has been investigating into the truth of the charges of barbarity on the part of American soldiers which have been widely disseminated throughout this country by means of letters from soldiers in the field. Mr. Worcester, after a careful probing of the matter, finds that these charges are "in the main grossly exaggerated and in some cases absolutely false." Referring to the story of a man who is reported to have said that "we bombarded a place called Malabon and then went in and killed every native we met—men, women, and children," Professor Worcester states that not only were no natives massacred, but that Malabon was never even bombarded, for the very excellent reason that it was abandoned by the natives before the approach of the United States troops. He goes on to say: "I have personally inspected all battlefields from Caloocan to Malolos. Once I was on the field before the wounded were removed, and repeatedly I was there before the dead were buried. I never saw a single woman or child wounded or dead. I have found, on the contrary, wounded rebels whose injuries had been dressed by American surgeons before the firing had ceased, and who had also been provided with food and

water. The insurgent wounded were brought to Manila and tended in our hospitals or even taken care of in private hospitals, the government paying all expenses. When cured the wounded can hardly be driven away. All the prisoners are well fed and treated, and many say that they are glad they have had the experience and learned to know the Americans. The released prisoners and the recovered wounded are our best missionaries, but many of them are unwilling to return to their own people." This emphatic testimony given by an unbiassed and upright witness should go far to counteract the false evidence which is for an unworthy purpose published in some American papers. The fact should also not be lost sight of that the publication in our journals of alleged atrocities are copied by the insurgent press, tending to prolong the war and to cause further misery and distress. It is not the insurgents alone that suffer, but, in the words of Professor Worcester, they cost good American lives.

**Self-Supporting Dispensary and District Nursing-Association in Great Britain.**—In a paper on this subject, Dr. Jamieson B. Hurry began by a discussion of the normal sickness rate of the population in order to prove how common a contingency is disabling sickness. Statistics show that during the working years of life, from the age of fifteen to sixty-five, each person is on an average thrown out of work by sickness for nine days per annum; but if the population is considered as a whole, women and children being included, Dr. Billings estimates that about four hundred out of every thousand individuals are taken ill or meet with accidents each year. It is of great importance that the industrial classes should make some provision for this contingency, since otherwise their limited resources are easily crippled by the expenses of medical attendance and nursing, if these have to be paid for at the usual rates. Even one serious illness or accident in a family may absorb the earnings of many weeks or months. The difficulty is not satisfactorily solved by hospitals, free dispensaries, free nursing-institutions, or poor-law relief; nor should the self-respecting workingman be willing to resort to charitable institutions for the treatment of the ordinary ailments that occur in every family. The only satisfactory solution is to be found in the adoption of the principles of mutual assurance. Such principles as are embodied in provident dispensaries and clubs have for many years been recognized as far as medical attendance is concerned, but the time has come when they should also be adopted in the provision of nursing, since there is no more reason why skilled service should be given in the form of free nursing than in the form of free medical attendance. Nursing is frequently as important as medical attendance. Indeed, the doctor and the nurse should be regarded as twin forces, each of which apart from the other loses half its value. Dr. Hurry's scheme is an organization for supplying the wage-earning classes with both professional and nursing attendance on a co-operative, self-supporting basis. The principle upon which the model institution is established is one of mutual assurance. Each member, by paying a small sum regularly and in advance, is guaranteed professional attendance, medicines, nursing-care, and the use of nursing-appliances when sick, subject to the rules of the institution.—*Medical Magazine.*

**Angina Pectoris.**—Sir William Broadbent (*Medical Age*, March 10th) is credited with the following remarks: "Angina pectoris is one of the cardiac affections which may be closely simulated by the effects of dilatation or functional derangement of the stomach. The first question to be put in the case of cardiac pain of anginoid character is as to the circumstances under which it comes on—whether as an effect of exertion or during repose. The earlier attacks of true angina are practically always provoked by exertion, while spurious angina is specially liable to come on during repose. It is true that angina when established may come on in the night, or may be induced by the act of undressing and the contact of cold sheets, but there will be a history of attacks during exertion. Pain and a sense of suffocation may also be brought on by the pressure of the abdominal viscera reinforcing that of a distended stomach on lying down, whether the heart is diseased or sound, and a weak heart may actually be brought to a standstill in this way. Speaking generally, angina pectoris in a woman is always spurious, and the more minute and protracted and eloquent the description of the pain, the more certain may one be of the conclusion. Again, when palpitation or irregular action of the heart, or intermission of the pulse, or pain in the cardiac region, or a sense of oppression follows certain meals at a given interval, or comes on at a certain hour during the night, there need be little hesitation in attributing the disturbance, whatever it may be, to indigestion in one or other of its forms. Nightmare from indigestion is not a bad imitation of true angina. So, also, if any cardiac symptom or pain can be walked off, it may usually be set down as functional, and due to some outside disturbing influence or to nervous irritability. The same may generally be said of intermission of the pulse, of which the patient is conscious, and, though with less confidence, of irregularity of the heart's action—if the patient feels it the irregularity is usually temporary, and not the effect of organic disease."

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ending July 22, 1899:

### THE QUESTION OF GRUELS IN THE FEEDING OF INFANTS.[1]

BY HENRY DWIGHT CHAPIN, M.D.,

NEW YORK.

DURING the past decade, the advances that have been made in substitute infant feeding have been marked and satisfactory. Every factor in connection with the production and handling of cow's milk has been carefully studied and regulated. The outcome has been that the greatest attention to strict cleanliness is insisted upon, and, if milk must be kept beyond a certain length of time, pasteurization or sterilization to prevent deleterious changes is employed. After having procured a clean milk, attention has been directed to attaining a right percentage of the various ingredients of cow's milk in reference to women's milk. The careful studies made in this direction have been a great step in advance, and enable us to administer to the infant a proper proportion of food principles necessary to its satisfactory growth and agreeable to its digestion. It has seemed to the writer, however, that with this advance we are in danger of neglecting some things that long clinical experience has proven to be good. The principal trouble lies in the difficulty many infants have in digesting the casein of cows' milk, even when reduced to the same proportion as in women's milk. We are told by physiological chemists that the casein of different animals is not the same, and that the casein[2] of cows' milk differs chemically from that of women's milk. We know that it differs physically, as the proportion of casein coagulated by acids is greater in cows' milk than in women's milk, and the clot in the former case is tough and tenacious in character.

The best method of acting on the casein of cows' milk in the way of attenuating and modifying the clot is by properly diluting the milk with a decoction of the cereals. Although this has long been believed, it has been denied on good authority, so that the writer instituted a series of experiments for the purpose of further studying the question. The writer extends his thanks to Professor Graham Lusk for the use of his physiological laboratory at the University Medical College, and for his kind co-operation in the work. The following three solutions were treated with liquid rennet: (1) Plain cows' milk, 50 c.c., (2) cows' milk 25 c.c., water 25 c.c.; (3) cows' milk 25 c.c., barley-water 25 c.c.

Each tube was inverted three times and warmed to 40° C. on a water bath. Then 3 c.c. liquid rennet was added and each tube again inverted three times. The tubes were allowed to stand for ten minutes at a temperature of 40° C. Each tube was then inverted three times, and the contents were poured into large glass beakers. The following were the results: (1) Solid clot; (2) large, tough clots; (3) smaller, more flocculent clots. After standing until the clots had subsided to the bottom of the beakers, the supernatant fluid in (2) and (3) was carefully decanted to allow a more careful inspection of the clots. A mass of clot from (2) and (3) was next placed in separate test-tubes and well covered with water. Each test-tube was then inverted three times. This agitation caused the clot in (3) to break apart, but that in (2) retained its cohesiveness. These experiments were repeated several times, with the same results, with one exception. In this case, tough, stringy clots were thrown down by the rennet in the solution of barley-water and milk, and we were at a loss to account for this result so different from all the other experiments. It was finally found that, by mistake, a preparation of barley-water two days old had been used, instead of a freshly prepared solution. This barley-water was fermenting and very acid. When fresh barley-water was used, the small curds were thrown down as before. This shows the necessity of always using a freshly made gruel as a diluent of cows' milk if a favorable effect upon the curd is to be obtained. An experiment in digesting clots (2) and (3) was made as follows: Portions of each clot of similar size were placed in beakers and covered with artificial gastric juice. They were then placed in an incubator and kept at the temperature of the body for twelve hours. The contents of beaker (3) were apparently more fluid and changed by digestion than beaker (2).

The next experiments were made with a healthy dog with a gastric fistula that had been produced for the purpose. The experiments were performed on consecutive days, early in the afternoon, the dog having fasted from the previous evening.

(1) 50 c.c. milk and 50 c.c. barley-water were mixed, warmed, and given to the dog by mouth. This solution remained in the stomach for ten minutes, when the fistula was opened and the contents of the stomach were removed, consisting of 85 c.c. of changed milk with the addition of some frothy mucus. The reaction was slightly acid to litmus paper. The stomach was then washed out with distilled water, the water coming away clear. The stomach contents were placed in a glass beaker for inspection. The milk was clotted, with the curds fairly soft and flocculent.

(2) 50 c.c. milk and 50 c.c. water were mixed, warmed, and given to the dog by mouth. At the end of ten minutes the fistula was opened and 90 c.c. of semi-fluid contents were removed. The reaction was slightly acid to litmus paper, but tests showed there was no free acid in the contents removed. The stomach was washed out with distilled water. The stomach contents were placed in a glass beaker for inspection. The clots tend to separate in larger masses than in experiment (1). These experiments were repeated with essentially the same results.

(3) 50 c.c. milk and 50 c.c. barley-water were mixed, warmed, and given to the dog by mouth. This solution remained in the stomach half an hour, when the fistula was opened and the contents were removed. The reaction was very acid. The curds were fairly fine and disseminated through the mass, apparently partially digested.

(4) 50 c.c. milk and 50 c.c. water were mixed, warmed, and given to the dog by mouth. The mixture remained in the stomach half an hour, when the fistula was opened and the contents were removed. The reaction was very acid. The curds were larger and collected more in masses than in experiment (3).

Besides attenuating the casein, the addition of gruels to cows' milk increases the nutritive value of the food. This is of great service in that class of cases in which bottle-fed babies show stationary or losing weight. The food for such infants may be properly prepared as far as percentages are concerned, and yet they do not thrive. This is especially seen in institution babies. A proper addition of gruels to milk will not infrequently check wasting. The large proportion of lactose, a carbohydrate, in woman's milk shows the desirability of this food principle to the growing baby. The rapid production and easy dissipation of animal heat in the very young, with active tissue metabolism, indicate the call for some of the carbohydrate series.

Various observers have called attention to the favorable effect of carbohydrates in tending to prevent the putrefaction of proteids in the bowel. Such action is doubtless due to the formation of acids in the intestine, especially in the lower segments. The presence of free acids in the bowel prevents the growth of those intestinal bacteria that thrive in an alkaline medium.

While proper theorizing is desirable in the practice of medicine, the ultimate and final decision upon any therapeutic question must rest upon clinical experience. The writer has tried all kinds of infant feeding with that hardest class of cases, bottle-fed babies in hospital and dispensary practice. By adding gruels to the milk, the best results are obtained with these babies. The theory is that the cereal will help attenuate the curd of cows' milk and aid in the nourishment of the baby; in practice, the infant is not so apt to vomit thick curds, and the tendency to a stationary or losing weight is often lessened. Jacobi, with his long clinical experience, while recognizing and utilizing all the advances in infant feeding, maintains that the use of decoctions of the cereals is of the greatest value as an addition to cows' milk. He finds that even very young infants thrive better when cows' milk is diluted with gruels than when a mere sugar solution is added. In Germany, Heubner, of Berlin, comes to the same conclusions from a wide clinical experience.[1]

The common objection advanced against this method of feeding is that a nursling should not be given starchy food in any form, as its digestive powers cannot cope with this food principle.

While large quantities of starch should be withheld in infancy, even the youngest baby can tolerate and digest a small and proper amount. According to Hammarsten,[2] ptyalin, or salivary diastase, the amylolytic ferment of the saliva, occurs in new-born infants. He also states that pancreatic diastase, which, according to Korowin and Zweifel, is not found in new-born infants and does not appear until more than one month after birth, seems, although not identical with ptyalin, to be nearly related to it. Hence a certain amount of starch can be digested by the newly born and very young infant. It may be of interest in this connection to glance at one of the more recent analyses of the amount of starch in certain cereals, in comparison with older analyses. Reference is made to a report of the United States Department of Agriculture[3], upon the carbohydrates found in wheat and maize. These important cereals are shown to contain a large variety of carbohydrates, among which the following have been quantitatively determined:

| | Per cent. |
|---|---|
| Sucrose | 0.2 to 0.70 |
| Invert sugar | None " 0.08 |
| Dextrin | 0.3 " 0.40 |
| Starch | 30.0 " 42.00 |
| Pentosans and hemicelluloses | 4.0 " 5.00 |
| Fibre | 2.0 " 2.50 |

The older analyses hold that the cereal grains contain from seventy per cent. upward of carbohydrates, although the foundation for this rests not on specific analytical determination, as in the above analysis, but on estimates "by difference." Thus the newer analysis shows a discrepancy amounting to twenty per cent. or more of the entire material between the actual amounts of carbohydrates found in the materials studied and the amounts indicated in many of the recorded analyses in which the nitrogen-free extract determined "by difference" has been regarded as wholly of carbohydrate matter. This discrepancy introduces not only important errors into the estimation of the nutritive value of foods based on the earlier analyses, but on their digestibility as well. Any disadvantage in the employment of wheat or barley flour from the starch contained in these cereals in very young infants may be easily overcome by dextrinizing the gruels. In an article upon infant feeding some years ago,[1] the writer demonstrated that the prolonged domestic heating of flour had no effect in changing starch into soluble starch and dextrin, as was then supposed. The flour ball, made by prolonged boiling of wheat flour in a bag, does not have a good effect by reason of any chemical change in the starch, but probably in consequence of some physical alteration which renders it more effective as a diluent. An easy, rapid, and simple method, within reach of all, consists in dextrinizing the gruel by the addition of diastase. Most of the commercial malt extracts are sufficiently active in diastase to produce the desired effect. The writer, however, prefers the use of diastase itself as being both speedy and efficient. It can either be produced cheaply at home or purchased at the nearest drug store. A simple decoction of diastase may be made as follows: A tablespoonful of malted barley grains, crushed, is put in a cup and enough cold water added to cover it, usually two tablespoonfuls, as the malt quickly absorbs some of the water. This is prepared in the evening and placed in the refrigerator over night. In the morning the water, looking like thin tea, is removed by a spoon or strained off, and is ready for use. About a tablespoonful of this solution can be thus procured and is very active in diastase. It is sufficient to dextrinize a pint of gruel in ten or fifteen minutes. The gruel is made as follows: A tablespoonful of wheat flour or barley flour is beaten up into a thin paste with a little cold water and then stirred in a pint of water, which is boiled for fifteen minutes. When cool enough to be tasted, a tablespoonful of the above solution or a teaspoonful of malt extract or preparation of diastase is added and the mixture stirred as further cooling takes place. The great bulk, if not all of the starch, will be thus dextrinized in about fifteen minutes. The previous boiling is for the purpose of gelatinizing the starch so that the diastase can act to advantage. The gruel is now ready to be used as a diluent of cows' milk, and can be assimilated by the youngest and weakest infant.

In average cases, and if the bowels tend to loose-

ness, wheat or barley flour may be used. When there is constipation, oatmeal had better be employed on account of the fat it contains. According to Dietrich and König, the percentage of fat in these cereals is as follows: Barley, 2.09; wheat, 1.55; oats, 6.09. It is difficult to procure barley flour, except as it is to be purchased in the form of prepared barley by certain manufacturers. Some coffee-grinders are fine enough to make a coarse flour out of pearl barley, and a satisfactory gruel can thus be made. The barley grains themselves, however, may be used if flour is not available. A tablespoonful of barley is soaked over night in a little cold water. This water is then removed and the barley boiled for five or six hours in a pint of water, replenishing the water as it evaporates below the pint. It is then strained and ready for use. As wheat flour is procurable in every house, it is a desirable basis for making gruels. In hot weather dextrinized gruels constitute a refreshing and nourishing drink for babies when milk in every form must be temporarily abandoned. Recently some foreign observers have claimed excellent results in infant feeding by the use of what they call "malt soups." In the MEDICAL RECORD for January 14, 1899, a quotation is given from the *Deutsche medicinische Wochenschrift* (September 28, 1898) in reference to some investigations made at the Breslau University Children's Clinic. Satisfactory results were obtained with a food made of 50 gm. of wheat flour stirred into one-third of a litre of water at 50° C., and adding to this 10 c.c. of an eleven-per-cent. solution of potassium carbonate. A malt-extract mixture is then stirred into the preparation of flour and milk, and the whole cooked together. Rapid gain in weight is reported in twenty-eight infants under six months fed upon this food. It was also found to be adapted to cases of gastro-intestinal disease.

Professor Graham Lusk has narrated to the writer some experiments he made in feeding pigs two days old. To one lot he gave only cows' milk skimmed; to another, skimmed milk to which two per cent. of sugar was added; and to a third, skimmed milk with two per cent. dextrose. The first lot did not thrive; the second did fairly well, while the third grew vigorously. The explanation may be that dextrose is the normal blood sugar and hence useful to the young animal.

## ANGIONEUROTIC ŒDEMA AND ALLIED CONDITIONS; REPORT OF SEVEN CASES.[1]

BY B. ONUF (ONUFROWICZ), M.D.,

NEW YORK,

LATE LECTURER ON NERVOUS AND MENTAL DISEASES IN THE NEW YORK POLYCLINIC; ASSOCIATE IN PATHOLOGY AT THE PATHOLOGICAL INSTITUTE OF THE NEW YORK STATE HOSPITALS; ASSISTANT NEUROLOGIST TO ST. CATHERINE'S HOSPITAL.

IT is the purpose of this paper to show from the observation of seven cases seen in private practice how closely angioneurotic œdema is allied to urticaria, certain forms of erythema, and some other disorders, all of which may be considered as being due to disturbances in that part of the nervous system which presides over the vegetative functions of the organism. The following are the cases upon which the writer's conclusions are based:

CASE I.—S——, male, twenty-four years old, came to my office for treatment of a spotted, somewhat measle-like exanthema on his arms, back, and front of chest. The chest was nearly evenly red, the eyelids were œdematous, and the lips thick and swollen. There was no pain, but itching. There was strong tremor of the hands and tongue. The patient admitted the abuse of alcoholic beverages, chiefly beer. He reported that the condition described was then present for the third time. The first attack occurred three weeks previously. Each of the two preceding attacks lasted three or four hours. The condition present in this case must be called an erythema of neurotic origin combined with angioneurotic œdema of the lids and lips. The fact of the abuse of alcohol is worthy of notice.

CASE II.—Miss W——, twenty-one years of age, came under my observation September 11, 1895. She reported that five days before, after a cold bath, she was taken with pain in the entire body and extremities, chilly feelings, and headache. On the day when she called at my office two kinds of eruptions had appeared on her body; one had the character of erythema; the other, according to the description which she gave of it, must have been urticaria. Both eruptions came and went and appeared again. On examination only the erythema was found, the urticaria having disappeared. After three days she felt perfectly well, the eruptions having permanently faded. The neurotic character of the eruptions in both these cases was indicated by the rapid fluctuations, the rapid coming, disappearing, and reappearing of the single attack.

CASE III.—Adam L——, thirty-three years of age. His family history was negative regarding urticaria or similar affections. About one year ago he had two attacks of the same illness from which he is suffering now; they lasted about one week each and were separated by a free interval of four days. The present attack began two days ago. Since then the patient has had four paroxysms of the following kind, each lasting between three and five hours: First, intense itching, beginning on the head, then spreading all over the trunk and extremities. This is accompanied by an eruption, evidently of urticaria; further by a feeling of heat over the whole body, profuse perspiration, dyspnœa and oppression; but otherwise there are no unpleasant sensations within the thorax, and no cough. The eruption disappears gradually, and is followed by nausea and a burning and tearing sensation in the epigastrium which gastric symptoms last about half an hour and conclude the paroxysm. Since last night there is swelling of both hands, affecting the dorsum, palm, and the fingers which latter were at first so stiff that he could hardly move them. The lower lids and adjacent portions of the face also show œdematous swelling dating from the same time. The patient denies having eaten berries or lobster or anything unusual. For several days before the occurrence of the first paroxysm he suffered from anorexia.

Status præsens: Marked œdema of the lower lids and the adjacent portions of the face, and also œdematous cushion-like swelling of the dorsum of both hands, but without itching. There was no urticaria eruption. The tongue was coated, with a foul odor from the mouth. Anorexia was present. The abdomen was considerably bloated. Urine: specific gravity 1.030, no albumin, no sugar; temperature, 101.5° F.

The further course of the attack could not be followed, as the patient was not seen again. We had in this case paroxysms evidently of urticaria alternating with or followed by an œdematous condition of the face and hands. The urticaria paroxysms were accompanied by visceral symptoms, due possibly to an urticaria-like condition of the mucous membrane of the respiratory and gastro-intestinal tracts. The œdematous state of the lids, face, and hands can hardly be due to kidney disease. The rapid, almost sudden appearance of the œdema in full intensity, its combination with paroxysmal urticaria, its manner of distribution, involving, as it did, the lids and hands, while the feet were left free, and, finally, the absence of albuminuria, speak decidedly against the renal and

[1] Read before the Brooklyn Neurological Society, February 24, 1898.

in favor of the neurotic origin of the œdema. I would call attention to the high specific gravity of the urine found in this case.

Case IV.—Miss X——, about seventeen years of age. Her mother suffers from hysteria, having been afflicted with hysterical deafness for many years. Her father and one of the patient's brothers are subject periodically to an affection which is evidently angioneurotic œdema: when going out in cold weather, their hands become swollen, which swelling subsides soon after entering a warm room. The patient herself some years ago had a transient hemiplegia, apparently of hysterical nature. On November 15, 1897, the following notes were made: The last two months the patient has been overworked with night study. Four weeks ago she began to grow nervous and to have long crying spells. She lost her appetite, and for the last three weeks has been complaining of burning and a feeling of sand and pins in the eyes. Objectively there was only a slight catarrh of the conjunctiva, but great irritability of the latter and a tendency to lacrymation and photophobia were present. More or less simultaneously with the eye symptoms the following condition developed: Almost every morning on arising the nose and eyelids are swollen. This swelling is gone within about twenty minutes, and usually no other cutaneous manifestations appear until she goes out, when the wrists and feet begin to swell, the latter so much that the buttons break off her shoes. The swelling is preceded by itching and a feeling of heaviness and clumsiness, but these subside when the intumescence sets in. The swelling is partly circumscribed, cushion-like, and not superficial.

The part affected is at first slightly reddened, but afterward white. The wrists are swollen *in toto* but mostly on the dorsum, where the swelling is cushion-like. The feet show a cushion-like, circumscribed swelling on the dorsum, and there is an even swelling of the whole foot and of the lower part of the leg. Aside from the regions mentioned the areas most frequently involved are the lips, which become thick, the forehead, on which sometimes a bump-like intumescence appears, and the fingers, which at times show thickenings much like that from the sting of a bee. The cutaneous swellings mentioned appear several times daily, lasting about twenty minutes at a time, but the writer has never had an opportunity of seeing them personally. The other parts of the body are seldom involved. On the part of the gastro-intestinal tract the patient shows no symptoms except the loss of appetite, dyspepsia, and a coated tongue. There is no pain in the abdomen. The features characterizing this case from an etiological point of view were the exquisite general neuropathic heredity and the angioneurotic heredity in particular. The case seems to be one of typical angioneurotic œdema, accompanied by psychical symptoms, pointing to an involvement of the whole central nervous system. The visceral symptoms were confined to loss of appetite and disturbed digestion, and absolutely lacked the paroxysmal and, I may say, active character, which we would expect if they were the expression of angioneurotic changes of the viscera.

Case V.—Miss L. W——, eighteen years of age, came to my office on November 9, 1897, giving the following history: Her mother and two sisters are nervous. The younger sister, now fourteen years old, suffers from insomnia, began to menstruate before the age of twelve and menstruates very profusely every two weeks. The other sister menstruates irregularly and has urticaria frequently. The patient is also nervous and has had urticaria several times. Regarding the causation of the present illness the following points are to be considered: For some years the patient, who formerly lived in good circumstances, has had to work for her living. For the past month she has been doing millinery work in a badly lighted and badly ventilated basement. Her occupation was mostly sitting and tired her greatly. For the last three or four weeks she has noticed a foul odor from the mouth and eructations of gas. There is some constipation, but no pain in the abdomen. She was a merry, lively girl before, but in the last week or two has become languid, sad, and cries very easily. For the past week she has had swellings in different parts of the body. The face sometimes swells up in such a manner that her mother thought it was dropsical; the eyelids become puffed up, the lips grow thick. Swellings appear also on the trunk, arms, and legs; some are similar to "hives."

Status præsens: Well-nourished girl. There are slight puffiness of the lids and irregular red spots on cheeks and nose. The lips look somewhat thick. On the front of the chest are several irregular red, non-elevated patches, due to local capillary vasodilatation. On the middle of the dorsal surface of the right forearm there is a hard swelling, resembling in shape and consistence a deep bruise. It is about three inches long and two inches wide. In this area there is hard infiltration not only of the cutaneous but also of the subcutaneous tissue. There is no such abrupt, steep, local elevation of the skin, with involvement mostly of its outer layers, as we find in urticaria; the passage from the normal skin to the swollen part is, on the contrary, gradual. In other words, the infiltration resembles more a contusional or phlegmonal affection in shape and consistence. The swollen area is reddened, but shows hardly any tenderness to pressure. On the left forearm is a longitudinal reddened strip with several infiltrations and several irregular red patches without any infiltration. On rubbing the unaffected parts of the forearm some new irregular hyperæmic patches make their appearance. The fingers and hands show little swellings, some white and some red, looking like mosquito bites. In the right gluteal region, over an area of six inches in diameter, the skin is elevated as in urticaria; but this elevation is higher and irregular, comparable somewhat in shape to an accumulation of varicosities. In this area the skin is not reddened but white. The patient reports that this one area was built up by the confluence of smaller swellings. The tongue is coated. Otherwise there is nothing to be noted regarding the gastro-intestinal tract.

In the observation just reported we note an exquisite general neuropathic heredity and a vaso-neurotic family taint in particular (anomalies of menstruation in two sisters, frequent urticaria in one sister). The exciting causes seemed to have been psychical factors and chiefly fatigue from unaccustomed work done under bad hygienic conditions. Symptomatically, the patient presented a beautiful combination of typical angioneurotic œdema with fugitive maculated erythema and with a condition which resembled urticaria very closely, differing from it only by the large dimensions of the single swollen patch and by the apparent absence of itching. In this patient, too, the cutaneous manifestations were accompanied by distinct psychical alterations chiefly of the emotional order.

Case VI.—Miss X——, thirty-two years of age. The family of this patient shows a very marked neuropathic and psychopathic heredity. With regard to special predisposition to viscero-neural disease, we note severe asthma in a brother, frequent attacks of facial herpes zoster in another brother, and paroxysms of diarrhœa under the influence of fright or anxiety in the mother. The patient herself has for years been a sufferer from enteritis tubulosa or membranacea. In childhood she had whooping-cough and measles, and at the age of about fifteen years diphtheria and typhoid fever. Between the ages of sixteen and twenty years during the summers, she was very languid, apathetic,

sleepy and weak, evidently because of anæmia. After that, her general health became good except for a chronic atony of the intestines and occasional paroxysms of violent pain in the lower part of the abdomen. Whether the expulsion of muco-fibrinous cylinders, to which the patient was subject, stands in any causal connection with these paroxysms of pain, could not be made out with certainty, but it seems very probable. At the age of twenty years after her first attempt at skating, the patient suffered a swelling of the feet and legs lasting several days. This may have been her first attack of angioneurotic œdema, but an exact description is not obtainable. Several years afterward a similar attack occurred, and since then several more have followed. The patient believes that the usual cause was prolonged standing, walking, running, or the like. On January 21, 1898, the following further notes were taken: About two weeks ago peculiar attacks appeared, consisting in a feeling of warmth in a circumscribed spot on the anterior surface of the left leg and usually caused by some emotion and disappearing with the latter. The sensation was localized every time at exactly the same spot. Since yesterday circumscribed swellings on both feet have attracted attention from a feeling of heaviness (although she sometimes has had the heaviness when no swelling was present). Since four days menstruation has been present. Otherwise no apparent cause of the swelling elicitable, except that a few days ago she had severe pain in the abdomen which woke her up in the night.

Status præsens (on January 22, 1898): On the left foot, in front of the external malleolus and about midway between the latter and the dorsum tarsi, a circumscribed swelling is seen, about one to one and one-half inches in diameter, with the consistence of a lipoma and showing no pitting on pressure. The swelling is white and not hyperæmic, but the veins of the dorsum of the foot stand out prominently. The remainder of the foot shows nothing remarkable and no œdema. On the right foot are two swellings, one in front of the external malleolus, the other over the dorsum tarsi. Both swellings show the characteristics described for the left foot. On strong dorso-flexion the swelling over the dorsum tarsi becomes somewhat more tense. In this position of the foot one feels distinctly that the swelling involves the deeper tissues, namely, the subcutaneous and possibly the intertendinous, while the superficial layers show the absence of swelling by the fact that the skin can easily be thrown into folds over the affected region. Over the other swellings mentioned, the skin is also easily wrinkled. When the patient arose the next morning the swellings were still present, and of about the same intensity as the day before. The urine is light colored; specific gravity, 1.018; no albumin, no sugar. There is no intestinal disturbance at present. This case, like the previous two, offers a striking family history of neural and especially of visceral neural disease. Symptomatically the case derives interest from the combination or alternation of angioneurotic œdema with enteritis tubulosa or membranacea, and with paroxysms evidently of intestinal colic.

Case VII.—F——, male, about thirty-five years of age. No satisfactory family history was obtainable. The patient himself is greatly psychopathic, subject to attacks of uncontrollable anger, chiefly when under the influence of alcohol, in which he indulges excessively. For many years he has been a sufferer from attacks of angina pectoris, characterized by extreme precordial anxiety and oppression, a sensation as if he was going to die, feeling at the same time as if the heart ceased to beat. These attacks are brought on chiefly by mental exertion, worry, or excessive use of alcoholic beverages. The patient is subject at times to unilateral sweating and unilateral redness, chiefly of the head and chest. Attacks of angioneurotic œdema have appeared only lately. On the day of the examination he had a large bump on the forehead which had the consistence of a bruise. The skin is slightly reddened over the swollen part. The swelling is mostly subcutaneous and does not pit on pressure. It lasts several hours at a time, then disappears, and after a time reappears in another place. It is not painful and causes no itching. Examination of the heart shows the absence of any organic heart lesion.

The prominent etiological features of this case were the marked psychopathic taint and the alcoholism. Symptomatically, the chief interests lay in the fact that the patient had attacks not only of angioneurotic œdema but also of angina pectoris of a decidedly neurotic nature, and that he was at times subject to unilateral sweating and unilateral vasodilatation.

I shall now proceed to an analysis of the seven cases reported, as respects etiology, symptomatology, diagnosis, prognosis, treatment, and nosology.

**Etiology of Angioneurotic Œdema and Allied Conditions.**—We have to consider (*a*) predisposing causes and (*b*) exciting causes.

(*a*) Predisposing causes: As predisposing factors we find that a neuropathic or psychopathic taint was the most important. It was present in four of the seven patients, and in three of these there was a marked general neuropathic or psychopathic family history. In the fourth case no satisfactory family history was obtained. In the remaining three of the seven cases reported, unfortunately the taking of the family history as regards nervous and mental disease was omitted. It is important to note that the four cases in which a general psychopathic or neuropathic taint was present showed also a special predisposition to vasomotor or viscero-neurotic disease. Three of the said four cases gave a family history: the first, of angioneurotic œdema in the father and a brother; the second, of urticaria and premature menstruation in one sister and of irregular menstruation in another; the third, of asthma in one brother, of frequent facial herpes zoster in a second, and of paroxysmal diarrhœa under emotional influence in the mother; and in the fourth case the predisposition of the patient to viscero-neural disease was apparent from his attacks of exquisitely nervous angina pectoris and from his being subject to unilateral sweating and unilateral redness. In looking for other predisposing factors, we find that in two cases alcohol played an important part. One of these was the case just referred to. In the other, alcoholism was the only etiological factor ascertained; other points were not inquired into. In the remaining two of the seven cases reported, the inquiry was also incomplete, so that in these it is questionable whether predisposing causes existed or not.

(*b*) Exciting causes: As to the exciting causes we have to note that in three cases (IV., V., and VII.) psychical influences of a depressing and fatiguing nature were prominent, but all three offered also a marked general neuropathic and a special viscero-neurotic taint.

The other directly causative factors found were bodily exertion in Case VI., alcohol in Case VII., and probably also in Case I.; an acute illness (influenza?) setting in after taking a cold bath and manifested by pain in the body and extremities, chilly feelings and headache in Case II. In one case (III.) no distinct direct cause was elicitable; the marked gastro-intestinal disturbances present here seemed rather to be effect than cause. It appears thus that the most frequent causative factors in the production of the individual attacks were psychical influences.

**Symptomatology.**—In many cases of angioneurotic œdema the viscera show such marked involvement that we are fully justified in speaking not only of cuta-

neous but also of visceral manifestations of the disorder. In adherence to this conception I shall consider first the cutaneous and then the visceral manifestations of the disease.

(*a*) Cutaneous manifestations: In defining angioneurotic œdema, we may say that it is characterized by the appearance of circumscribed, apparently transudative swellings produced by disturbances of vascular innervation. My friend Dr. Joseph Frankel has kindly called my attention to an article by Heidenhain wherein this author declares that the endothelial cells of the blood-vessels possess a secretory activity. If this statement should find confirmation it would explain in a much more satisfactory manner the process producing the swellings of angioneurotic œdema than the theories of modified permeability of the blood-vessel walls.

Although the definition of angioneurotic œdema as given above would cover also urticaria, the latter disorder is usually not included under that name. The cases reported by me show, however, the intimate relationship between these two conditions and also the close affinity of certain forms of erythema to angioneurotic œdema. It will be well to consider, first, the typical forms of angioneurotic œdema; second, the forms of urticaria combined or alternating with angioneurotic œdema, and, third, certain neurotic forms of erythema combined or alternating either with angioneurotic œdema or with urticaria, or with both.

The typical angioneurotic œdema manifests itself by circumscribed swellings. These may have a rather soft, almost lipomatous consistence, or they may be rather hard, much like contusion bumps, or very soft, puffy. Usually they do not pit on pressure and are thus easily distinguished from hydropic œdema; but in certain localities, as, for instance, the eyelids, the angioneurotic swelling has so completely the character of a hydropic œdema that by the swelling alone these two conditions could not be distinguished from each other. It further appears—and I found this very well marked in one of my cases—that the angioneurotic swelling, if very extensive, produces a collateral œdema, which bears absolutely the stamp of hydropic swelling, showing also pitting on pressure. But I wish to emphasize another point, namely, that the form of the angioneurotic swelling depends greatly upon the character of the tissue involved, chiefly upon the character of the subcutaneous tissue; where the latter is dense, as, for instance, on the forehead, the angioneurotic swelling will be hard; where it is moderately dense, as for instance around the ankles, it will be softer; and, finally, where the subcutaneous tissue is very loose, as we find it under the eyelids and over the dorsum of the hand, the swelling will be very soft and puffy and will bear close resemblance to hydropic œdema. In this regard the variations are quite similar to those of phlegmon in various localities.

Here it will be appropriate to remark that the difference between angioneurotic œdema and common urticaria lies chiefly in the fact that in angioneurotic œdema the subcutaneous tissue is much involved and the epidermis is free or almost so, while in urticaria the condition is the reverse, the most superficial layers of the skin being those mostly affected. If the angioneurotic swellings are extensive they may have some resemblance to myxœdema, yet they are mostly so circumscribed that a mistake can hardly be made. As to the color of the angioneurotic swellings, they are either slightly red or perfectly white, paler even than the surrounding normal tissue. So much for the typical angioneurotic œdema. Only three of the seven cases reported presented this disorder in its pure type. In all the other cases the types were mixed.

A mixture of angioneurotic œdema with urticaria alone was present in Case III. of our series. The patient had several paroxysms accompanied by cutaneous eruptions which according to his description must have been urticaria; but at the examination only angioneurotic swellings were found on the face and hands—the urticaria eruption had disappeared.

Erythematous conditions combined with urticaria or angioneurotic œdema, or with both, were found in three of the cases: In Case V. the erythema appeared in the form of irregular, red, not elevated patches, produced mainly by capillary vaso-dilatation. In Case I. it had the character of a spotted, somewhat measles-like exanthema on the arms and back, while the front of the chest was almost evenly red, evidently by confluence of the single patches. In Case II. detailed notes of the form of the erythema were unfortunately not taken.

All three cases had one thing in common—the fugitive and paroxysmal character of the erythema. The close affinity with urticaria was shown in Case II., in which urticaria and erythema were present at the same time. On the other hand, Case I. showed an exquisite combination of angioneurotic œdema in the face with erythema on the arms, back, and chest. And, finally, Case V. presented a combination of all three conditions, if we are allowed to consider the large superficial swelling found in the gluteal region as a giant form of urticaria; and, indeed, the description agrees well with this view.

It seems to me that this giant urticaria demonstrates in a convincing manner the close affinity between angioneurotic œdema and urticaria. It has in common with urticaria the topography of the lesion, occupying, as it does, the most superficial strata of the skin and causing thus an abrupt elevation of the latter. On the other hand the large extent of the swelling is much more in conformity with angioneurotic œdema.

All three affections, angioneurotic œdema, urticaria, and what we may call neurotic fugitive erythema, have in comomn the circumscribed character (although sometimes a confluence takes place), their usually sudden, paroxysmal coming and going and reappearing, and their causation by disturbances of vascular innervation.

We have now to consider the (*b*) visceral manifestations of the three conditions described. Here we should distinguish between passive and active manifestations or alterations. By passive manifestations I wish to designate those more secondary visceral, but chiefly gastro-intestinal symptoms, which accompanied the disease in some cases, and which absolutely lacked a paroxysmal character. These symptoms were anorexia, dyspepsia, and constipation, which were marked in Cases IV. and V. of our series. By active visceral manifestations, I understand active, that is to say positive, symptoms of a distinctly paroxysmal character accompanying the cutaneous manifestations or alternating with them. These were very distinct in Case III., in which the visceral paroxysms were characterized by a sensation of pressure in the chest and dyspnœa, followed by nausea and by a burning and tearing pain in the region of the stomach. In Case VI. there were very marked symptoms consisting in paroxysms of violent colic-like pain in the lower part of the abdomen, and in the expulsion from the intestine of muco-fibrinous cylinders representing, as it were, casts of the intestinal canal. In other words the patient suffered from the disorder known as enteritis tubulosa or membranacea. It is very important to note that one and the same patient suffered both from attacks of angioneurotic œdema and from attacks of enteritis tubulosa. This being the case, it is very suggestive to assume that the enteritis tubulosa or membranacea is an intestinal expression of a disorder similar to that which in the skin or subcutaneous tissue we know under the names of angioneurotic œdema and urticaria.

Regarding further symptoms of angioneurotic œdema we recall the marked psychical alterations which accompanied the disease in Cases IV. and V. An examination of the urine unfortunately was made only in two cases. In none of these was there albuminuria or glycosuria. In one of these the specific gravity of the urine was unusually high, but in this case there was some fever.

**Differential Diagnosis.**—Under this caption I wish to discuss only the differential diagnosis of angioneurotic œdema, since that of urticaria and the fugitive neurotic erythema should not cause any difficulty. In making the differential diagnosis of angioneurotic œdema the following conditions will have to be thought of: (1) Mechanical local œdema due to some local disease; (2) hydropic œdema; (3) the white œdema of hysteria; (4) the blue œdema; (5) Myxœdema; (6) insect bites or the like, (7) erythema nodosum.

(1) Mechanical local œdema due to some local disease: Certain lesions, such as aneurism, tumor, glandular swellings, thrombosis, or the like, may by pressure or in other ways produce a local venous stasis, and this stasis may result in a circumscribed local œdema which may be very difficult to distinguish from an angioneurotic swelling. Therefore, in making the diagnosis of angioneurotic œdema such local lesions ought to be carefully excluded. Of course the great variability of the clinical picture in angioneurotic œdema will go a great way toward confirming the diagnosis if the latter condition is present. We must keep in mind also that angioneurotic swellings are usually painless.

(2) Hydropic œdema: As a rule the angioneurotic swellings are so circumscribed that they can hardly be mistaken for hydropic œdema. But in some parts, such as the eyelids, the swelling may so closely resemble that of dropsy that its nature does not give us any diagnostic clew. In such cases, however, the distribution of other swellings will be of great help. If, for instance, the hands are swollen while the ankles are free, this will speak against dropsy and in favor of angioneurotic œdema. The points that must further guide us are the paroxysmal character, the rapid coming and going of the swellings in angioneurotic œdema, the absence of conditions (kidney disease, heart disease, anæmia) that may give rise to dropsy, and the fact that in case of dropsy the swellings are apt to decrease in the morning, which is not the case in angioneurotic œdema.

(3) White œdema of hysteria: In this affection the swellings are usually not circumscribed, as in angioneurotic œdema, but diffuse, evenly distributed, so that, if they affect the thigh for instance, this thigh is enlarged *in toto* and not in certain places only. Moreover, the white œdema of hysteria is frequently associated with hysterical motor or sensory paralysis or contracture of the affected limb, and other stigmata of hysteria will be found. But we must not forget that an hysterical patient may become affected with typical angioneurotic œdema.

(4) Blue œdema: This disorder, considered formerly as characteristic of hysteria, has lately been found also in other and especially organic diseases, for instance syringomyelia. The following considerations will facilitate the differential diagnosis:

(*a*) In all cases of blue œdema the latter has been preceded and accompanied by paralysis, paresis, or contracture of the limb involved.

(*b*) In the majority of cases the blue œdema involves only one limb, and it always occupies its extremity.

(*c*) The swelling of blue œdema is, as a rule, not circumscribed, but diffusely distributed over the part involved.

(*d*) The part affected with blue œdema shows a bluish or violet discoloration, and, in all reported cases except two, presented a local lowering of the temperature of several degrees Celsius, as compared with the normal side.

(*e*) In cases of the blue œdema of hysteria, hysterical stigmata will be found.

(5) Myxœdema: The angioneurotic swelling, if extensive, might occasionally bear some resemblance to myxœdema. The fact alone, however, that in the latter disease the condition is stationary will establish the differential diagnosis, since in angioneurotic œdema the swelling jumps from one place to the other.

(6) Insect bites: A sting of a bee or the like may sometimes look like angioneurotic œdema, but usually the region of the entrance of the poison is well marked in these cases, thus rendering recognition easy. In case of angioneurotic œdema the appearance of new swellings without visible cause will establish the diagnosis.

(7) Erythema nodosum: Although the nodes characterizing this affection may have very much the shape and consistence of angioneurotic swellings, the purple discoloration of these nodes, followed as it is by the color changes which we find in bruises, makes it almost impossible to mistake one condition for the other.

**Prognosis and Treatment.** The limited number of cases seen by me does not permit any positive conclusions as to the prognosis of the disease. It can be said only that in two of my cases of typical angioneurotic œdema, and in Case II., which was a combination of erythema with urticaria, the recovery from the attack could be directly traced. In the other four cases the course of the attack could not be followed to the end, as the patients were not kept under observation; but probably in all these cases recovery from the attack took place.

Collins has collected seventy-one cases of angioneurotic œdema from the literature, and from such a number more definite conclusions are of course warranted. It would appear then from this collection that the single attack of angioneurotic œdema leads usually to recovery in a few hours or days, and that it does not endanger life, except when the swelling affects the mucous membranes, especially those of the larynx and pharynx, where it may lead to suffocation. As to the liability to the recurrence of attacks, there was recurrence in three of my cases, while the four other patients were apparently suffering from the disease for the first time when they came under my observation, and whether other attacks have followed since could not be learned. Collins mentions that the disease may occur but once in a lifetime, but such assertion can, of course, be made only regarding cases which have been observed until death.

Regarding the treatment of the disease, my experience has been limited, owing to the fact that the majority of the patients were not under observation a sufficient length of time to show a result of therapeutic procedures. In Cases II. and V., recovery followed, although the treatment was rather negative. In case IV., in which an overtaxing of the mind seemed to be the principal cause, the installation of mental rest soon led to disappearance of the symptoms. When alcohol plays an important etiological part, as it did in Cases I. and VII. of our series, the removal of such a distinct cause will presumably be attended by success. On the whole, it would seem that in most cases a treatment directed toward a general strengthening and tranquillization of the nervous system would have the best chance of success.

In future observations more attention will have to be paid to the general condition, the presence of a rheumatic or lithæmic diathesis, of toxic or autotoxic influences, etc. A careful examination of the urine in

every case would be desirable. All these factors will, of course, influence the treatment to be pursued.

**Concluding Remarks.**—The nosological position of angioneurotic œdema is best defined by showing its close affinity with certain other diseases. The cases reported demonstrate convincingly this affinity with urticaria and the fugitive neurotic erythema. But there is apparently also a great resemblance to the so-called enteritis tubulosa or membranacea, except that here secretory innervation appears to be mainly disturbed, while in angioneurotic œdema the alteration affects chiefly vascular innervation. If we consider further the tendency to coexistence with angioneurotic œdema of nervous angina pectoris, anomalies of menstruation, or other disturbances, whether of vascular or of viscero-motor or of secretory innervation, either in the same individual or in his family, the following conclusion suggests itself:

Certain individuals are especially predisposed to disease of that division of the nervous system which presides over the vegetative functions of the organism. This special predisposition may be only individual or it may be hereditary. In either case it may extend over several vegetative functions or over one in particular. Thus, one patient may show predisposition to disorders of vascular innervation only; in another patient, if he suffers from asthma for instance, viscero-motor innervation may be exclusively disturbed; or—and of this our Case VII. is a good example—several vegetative functions of the nervous system, such as vascular, cardiac, and secretory innervation, may be involved in the same patient. In some cases finally the predisposition mentioned might produce the symptom complex known as Basedow's disease.

Be it mentioned in conclusion that what I have severally called viscero-neurotic taint, the predisposition to disorders of the vegetative functions of the nervous system, is frequently associated with a general neuropathic or psychopathic taint.

---

## REFLEX COUGH.[1]

By GEORGE L. RICHARDS, M.D.,

FALL RIVER, MASS.,

OTOLOGIST AND LARYNGOLOGIST TO THE FALL RIVER AND EMERGENCY HOSPITALS; FELLOW AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY, AMERICAN MEDICAL ASSOCIATION, ETC.

Like the poor, the cough is always with us. The infant of a day old coughs, as does the aged person whose life is almost run. Its varieties are many, its causes as various. Confronted as we are during our whole life history as physicians with this phenomenon, it might be thought that its diagnosis and treatment would have become one of the certainties of medicine. Alas, there are no certainties in medicine! So the patient who has tried various remedies at the hands of many physicians, and whose respiratory tract has been many times examined without finding the cause of the cough, is perhaps as a last resort sent to the nose and throat specialist in the hope that perhaps these organs will reveal the hidden cause of the cough. His history is taken, and the examination is made, beginning at the nose and ending at the lungs. Often one is rewarded by finding in the upper air tract sufficient that is pathological to account for the cough. Of almost daily occurrence is the cough of nasal origin, from enlarged turbinates, a deviated septum, a spur pressing on the turbinates, or a general hypertrophic condition of all the erectile structures; the cough from an elongated uvula, the cough of granular pharyngitis, the cough from hypertrophy of the pharyngeal and lingual tonsil (this latter one of the most frequent causes of tickling, teasing cough), and the cough of laryngeal origin. These are the cases in which results are frequently brilliant, and the cough of weeks, months, or even years quickly disappears; the patients sing our praises and help increase our practice.

There are many patients, however, for whose cough, after careful examination of the respiratory tract, no cause has been found; these are the coughs properly termed reflex, as no demonstrable lesion is found in the air tract from nose to terminal air vesicles. The term reflex cough includes all coughs extra-respiratory in origin, which are due directly or indirectly to irritation of the fibres of the pneumogastric nerve, whether peripheral or central. The term nervous cough is often applied to the coughs of central origin. Included in the term reflex are the coughs of pressure origin, as from aneurism, enlarged thyroid, and new growths outside of the larynx and trachea. Cough of nasal origin is in a sense not reflex, since the nose is a part of the respiratory tract, yet as it is not supplied by the pneumogastric but communicates with it through the vasodilator nerves from the superior cervical ganglion via the spheno-palatine ganglion of the sympathetic, it seems to me proper to call nasal coughs reflex within the meaning of my definition.

I except coughs resulting from the irritation of mouth breathing consequent upon nasal and naso-pharyngeal obstruction, since they are hardly to be classed as true reflexes. The whole subject of reflexes is still imperfectly understood, and theory seems more prominent than fact in our explanations of their occurrence. They seem as a rule due to peripheral irritation, though of central origin as well. The irritation passes along sensory fibres to the point of explosion in regions supplied by some other nerve, and when there is no direct communication travels via the sympathetic or some other ganglia. This accounts for the distant nature of some of the cough-producing reflexes. These reflexes have been known for many years, as Müller in his "Physiology" of 1843 wrote that irritation of any mucous membrane in the body could give rise to a respiratory reflex. In later years the whole subject has been studied with more care, and J. N. Mackenzie, Hack, Semon, Yearsley, and others have written upon it. It is at once evident that the pneumogastric nerve, with its wide distribution to vital organs and centres which it controls directly or indirectly, is the key-note of the subject and explains how manifold are the possible causes of reflex cough.

Superficially the pneumogastric nerve arises by eight or ten filaments from the lateral tract immediately behind the olivary body and below the glosso-pharyngeal; deeply it may be traced through the fasciculi of the medulla to terminate in a gray nucleus near the floor of the fourth ventricle. Its first branch, the auricular, arises from the ganglion of the root, receives a connecting filament from the petrous ganglion of the glosso-pharyngeal, passes through a narrow canal in the substance of the temporal bone, crossing on its way the Fallopian aqueduct, and is connected with the facial by ascending and descending branches. Emerging from the bone in the interval between the mastoid process and the external auditory canal, it ends by supplying the integument on the posterior surface of the ear. In connection with the great auricular with which it communicates, and the auriculo-temporal, it supplies the meatus, external canal, and integument of the ear. The pharyngeal branches supply the mucous membrane of the pharynx, communicating with the pharyngeal plexus of the sympathetic and with the glosso-pharyngeal.

[1] Read before the Eastern Section of the American Laryngological, Rhinological, and Otological Society, at its annual meeting, held in Washington, D. C., January 28, 1899.

The superior laryngeal branch is the nerve of sensation of the larynx, with motor fibres to the cricothyroid muscle. It supplies the mucous membrane of the interior of the larynx, base of the tongue, and ary-epiglottic fold, and communicates with the spinal accessory. The recurrent nerve supplies the other muscles of the larynx, has œsophageal, tracheal, and cardiac branches, and cardiac filaments communicating with the sympathetic. On account of the variation in its origin on the two sides and its relations to great vessels, the recurrent is especially liable to reflex disturbances and pressure symptoms. There are anterior and posterior pulmonary, cervical, and thoracic cardiac branches, forming plexuses and communicating with the third and fourth sympathetic ganglia. The œsophageal branches form plexuses with the pulmonary, while the gastric branches, the terminal ones, communicate with the sympathetic and with the hepatic plexus (condensed from Gray).

The phenomenon which we call cough is due to forcible expiration against a closed glottis. When a person prepares to cough not only are the vocal cords approximated but the margins of the ventricles of Morgagni are brought forcibly together, the whole forming a barrier to the exit of air until they are separated by the upward draught from the trachea. Any secretion which is readily detachable is at the same time brought up into the mouth and expelled. The cough is due to an irritation at some point which sets in motion through its afferent sensory fibres the explosive mechanism of the pneumogastric. This irritant may be in the respiratory tract or without, acting reflexly by irritation of the pneumogastric fibres.

The diagnostic points as to reflex and nervous cough should be pretty clearly in mind, since we are never forgiven for calling a cough reflex or nervous if it is afterward proven to have been otherwise. An absolute line of demarcation between organic respiratory and reflex coughs is impossible, since a cough which to-day might be labelled reflex may later be found to have its seat in the respiratory tract; the physical signs at the time of examination not having been sufficient for diagnosis. In the larynx small undiscovered ulcerations may produce a cough simulating nervous cough. The cough irritant is referred below the larynx, and pressure at this point will excite coughing when laryngoscopic examination shows no apparent change from normal. It is entirely possible to have a reflex cough engrafted on to real pathological conditions, or to have healed conditions eventuate in a reflex cough. Schrötter cites an instance in which there was a small laryngeal neoplasm; before removal there was no cough, after removal and complete healing a persistent cough appeared. Competent laryngologists could not find the site of the removed tumor, yet the cough persisted and was referred to the larynx.

Reflex and nervous cough is characterized by some or all of the following: Sudden appearance; rhythmical character; free intervals when no signs of cough are present, expectoration absent or slight in amount; no fever or marked constitutional disturbance; may continue for years or stop at any time, or eventuate in other symptoms, may come at regular intervals; stops when person's attention is fully occupied; is most marked when the patient is under observation; if stopped for a time begins with an explosion; is usually absent at night, always if purely nervous; absence of physical signs in respiratory tract; cough apparently a useless one, does not accomplish anything; patient complains of usual symptoms of catarrhal cough in the respiratory tract; its tone is various, sometimes hacking, bellowing, shrill, croupy, metallic, at other times hoarse from insufficient cord tension. This latter is an imperfect cough, and according to Professor Gardner is somewhat distinctive of thoracic tumors or aneurism pressing upon the recurrent laryngeal nerve. Its chief features are hoarseness and imperfect explosion; it is a noisy, not infrequently harsh, brassy cough.

With all the foregoing in mind, the diagnosis is frequently difficult. Especial care is to be taken that the early stage of severe affections, as neoplasms, aneurisms, and the like, be not confounded with purely nervous cough: though a reflex cough, it may be the earliest symptom of serious trouble. Newman, before the British Medical Association, July, 1898, stated that the early symptoms of aneurism or malignant disease were often referred by the patient to the throat and nowhere else.

The points from which reflex irritations eventuating in cough come are very various:

Those of central origin: While the central origin of nervous cough has never been proven, it is at least highly probable. The dorso-lateral portion of the root of the pneumogastric has been thought to be the seat of the changes giving rise to the phenomena. In this group are the coughs of laryngismus stridulus of children and adults, hysteria, chorea, tabes, epilepsy, and neurasthenia. I do not know that the average physician regards laryngismus stridulus (false croup) as a reflex phenomenon, yet such it is, and I have placed it among those of central origin. Various irritations excite the reflex. Combined with the irritation, whether of rickets, an overloaded stomach, or what not, there is always a hyper-excitability of the central nervous system. Gottstein calls it a pure neurosis, and Semon says it may arise from pressure on one recurrent, since in the child the glottis is so small that spasm of one cord may produce sufficient narrowing of the glottis to cause dyspnœa. Much more frequently the cause lies in direct or reflex irritation of the cortical centres. When one reflects upon the excitable nature of the young child's nervous system, and recalls that the attack usually occurs at night, often after a day's hard play, an overfilled stomach, or something of the kind, the occurrence of attacks of laryngismus stridulus is not difficult to understand. They seem to me to be on a par with the night terrors of children.

In adults, glottic spasm is most commonly due to hysteria. An example of this is seen in the following case:

Miss M. H——, aged fifteen years, large for her age; family history somewhat neurotic; seen by me on February 10, 1897, with history of three months' cough of the following character: at intervals varying somewhat, but about once a minute, at the time I saw her, she made with expiration a peculiar sound, nearer a cough than anything else, yet hardly a cough. It sounded more like the bleating of a sheep than anything else—"nah-am-ung." I was able to get a laryngoscopic examination during the paroxysm, and found the glottis almost closed, due to spasmodic contraction of the adductors rather than to paralysis of the abductors. There was no expectoration and the general health was unimpaired; control by the will was slight, and the cough never occurred during sleep. Treatment at the hands of the physician who referred her to me for examination was without avail. At the end of a year and a half the cough gradually disappeared, but hysterical manifestations still remain.

Another case probably of pure nervous cough (central origin) is the following:

D. B——, Hebrew, tailor, aged sixteen years, has a persistent hacking cough appearing at regular intervals and lasting a few seconds, one of the apparently useless coughs without physical signs, expectoration, or constitutional symptoms. Careful examination by several competent observers revealed nothing in the respiratory tract. In the left subclavian region an oc-

casional but not at all constant bruit was heard. The cough was not that of aneurism, nor could any sign of aneurism be found; it seemed to me to be of central origin. Remedies of various kinds were used without avail. This is one of the cases which was not wholly clear. If not a neurosis, I have so far failed to find the cause. It may possibly be an anæmic cough, for I imagine there is frequently some relationship between anæmia and hysteria.

Ebstein relates the case of an hysterical girl in whom the slightest irritation of any kind, sensible or emotional, produced coughing of the severest intensity.

The following case is one of paroxysmal reflex cough of usual severity:

Mrs. C. G——, wife of an army officer, somewhat neurotic in temperament, several times pregnant. When living in Baltimore some time previous to 1878, she had some kind of a benign tumor (painful, probably a fibroma or fibro-neuroma) removed from the region of the right shoulder-blade; for some reason the removal was not complete, and considerable pain in the region of the cicatrix remained, for which morphine in considerable doses was required. She removed to Detroit, where a paroxysmal cough appeared; this came at regular intervals of four hours during the daytime, beginning early in the morning. The cough was of terrific violence and had three explosions with each attack, separated by a few seconds' interval. At this time the cicatrix was supposed to be the exciting cause by involvement of the spinal accessory and reflexly the pneumogastric. She visited the Baltimore surgeon, who wished to operate again on the shoulder, but this she declined having done. From 1878 to 1884 she was seen by many physicians in Philadelphia, Baltimore, Washington, and Buffalo, without relief. In 1884 the cough disappeared, but in 1890 it returned in full force, and early in 1891 she came under my observation. The paroxysms were then perfectly regular as to time, coming at six, ten, two, six, and ten o'clock. There was a slight prodromal stage, then the paroxysm of coughing, lasting about five minutes, loud enough to be heard half a block away, and sounding somewhat as though a lot of furniture was being broken with a loud crash; the whole followed by a period of relaxation and weakness of perhaps ten minutes' duration. She was then entirely free from cough until the four-hour interval reappeared. There was no expectoration, but slight increase in pulse and no constitutional symptoms of any account were noted. If the patient was awake in the night, the cough would sometimes occur, never when she was asleep. The four-hour interval was absolute as to time; turning the clock back and efforts to fool her in this respect were without avail. Finding that chloroform to complete anæsthesia in the prodromal stage prevented the attack, and if continued for two or three consecutive times some of the subsequent attacks failed to appear, she suggested that I give her chloroform two days before each attack. To be sure of this she paid me in advance. I gave her chloroform at the prodromal period for ten consecutive times, and the cough ceased. This was on the 10th and 11th of May, 1891. She was under my observation for two and one-half years thereafter, without return of the cough. There was an occasional spasmodic contraction of the sternomastoid muscle producing a true wry neck, for which chloroform and morphine had to be given. She wrote me a short time since that the cough had recurred once since 1891, for a short time only. At the present time I am not aware that the old cicatrix is troubling her. This cough was a nervous one, with the cicatrix and its communication with the pneumogastric via the spinal accessory as the determiner of the reflex.

Reflex cough of uterine origin is common, and, as is well known, is often one of the early manifestations of pregnancy. Hegar records a case of reflex cough due to a retroflexed uterus, in which the cough stopped as soon as the uterus was replaced and came on again whenever the pessary was removed. Moritz Schmidt relates a case of cough apparently due to pyosalpinx.

Coughs having their point of irritation in the stomach, bladder, intestines, and liver are not infrequent. Dr. J. J. Richardson has reported a case of violent coughing from indigestion; this disappeared as the indigestion improved, only to reappear when the indigestion again became troublesome. The cough of tabes is a well-recognized one.

Ear cough is one of the rather common reflexes. It originates from pressure or irritation in the external canal. Schmidt refers to the case of a girl who had coughed for twelve years. The removal of a glass bead from the auditory canal stopped the cough. One of my patients, a medical man, has a cough whenever a speculum is introduced into the ear or the canal wiped out with a bit of cotton on a probe. Dr. Richardson instances a case of long-standing cough which ceased after removal of some disintegrated cotton and cerumen. The cotton had been introduced some years previously and forgotten Yearsley mentions cases of cough from impacted cerumen. Fox (quoted by Yearsley) concludes that the track of the reflex is not direct via the great auricular nerve, as has been thought, but that "the convulsion takes place in the nervous centres," and the nerves involved are the two branches of the auriculo-temporal and Jacobson's nerve. By these channels the stimulus is carried to the centres in the floor of the fourth ventricle, where the roots of the vagus and glosso-pharyngeal nerves lie in close connection. The stimulus being mistaken for laryngeal irritation, cough is the result. Stephens has recently reported in *The Lancet* eight cases of whooping-cough successfully treated by syringing the canal and painting it and the tympanum with a paint of cocaine, glycerin and mercuric chloride. This is on the theory that there is a local inflammation in the external canal and that this irritates the nerve filaments connected with the root ganglion of the vagus, thence stimulating the laryngeal branches. This theory of whooping-cough can hardly be called proven.

The exact track of the reflex in nasal coughs is not clear, but the facts are undoubted, since treatment of the nasal conditions cures the cough. This cough is characterized by a small amount of secretion compared with the severity of the cough, and usually starts with tickling in the inter-arytenoid region, as in the following case:

Mrs. S. W——, aged twenty-eight years, had an alarming paroxysmal cough, for which a change of residence had been advised by the family physician, who thought the lungs were involved. She was subsequently seen by several physicians without relief. Finally a specialist of note suggested that the nose might be the organ at fault. Cauterization of the turbinals cured the cough, which has never returned, although seven years have since elapsed.

For the notes of the two following cases I am indebted to Dr. Stucky, of Lexington, Ky., in whose practice they occurred:

Miss A. B——, twenty-three years of age, well-nourished, intelligent, and of neurotic type; menstruated at the age of twelve; at seventeen years her health became impaired and menstruation scanty, occasionally suppressed; there was dysmenorrhœa at times. These conditions lasted several years, during which time the cervix uteri was dilated, and both ovaries were removed. This cured the dysmenorrhœa but did no good otherwise. She was next operated on for vesical calculi and then for hemorrhoids. During a period of twelve years she was under the care of twelve physicians, and to quote Dr. Stucky's own words, "I con-

cluded that everything within the abdominal and pelvic cavities had been removed that could be with safety to life." At the time of the consultation she had a peculiar barking cough, like the yelp of a hound pup, which made the patient a nuisance to herself and to every one else within hearing distance. It continued during sleep, unless controlled by morphine, and was of increasing severity. She had been subject to head colds and sore nose since childhood. On examination, both inferior turbinates were found to be markedly hypertrophic from the anterior to the posterior extremity, the pharynx granular, and there was some spasm of the adductors of the larynx during phonation, with thickening of the false cords. No local treatment was at first employed, the patient being put on rest treatment on account of the marked neurasthenic element. The cough grew worse instead of better, and coincident therewith she had an acute attack of rhinitis, for which some ten-per-cent. cocaine was prescribed for temporary use. To the surprise of every one the cocaine not only relieved the nasal discomfort, but stopped the cough so long as the effect lasted. Some chromic-acid crystals were accordingly applied to the whole length of each inferior turbinate, producing immediate cessation of the cough and relief of the neurotic symptoms. In two weeks another application was made. The patient remains entirely relieved, and her general health is better than at any time since childhood.

The second case was that of a woman who had been the round of abdominal, rectal, and neurological specialists. The cough was of a most obstinate and spasmodic character, worse at night with frequent strangling spells. In one of these attacks (laryngismus stridulus) her symptoms were alarming for several minutes. Chromic acid to the enlarged inferior turbinates cured the cough.

In a case of my own now under observation, touching the turbinals with a probe will invariably excite a spasm of coughing.

Examples of cough from direct pressure on laryngeal structures are common:

Mrs. H. E. B——, aged forty years, had a troublesome, irregular, teasing, hacking cough, lasting ten minutes to half an hour, waking her in the morning. Its duration was two or more years, and it was growing worse. The pulse was 120 to 130; lungs negative; thyroid gland moderately enlarged; no appreciable tracheal pressure. Treatment of the thyroid by galvanism, with proper internal treatment, reduces the size of the gland and diminishes the cough. If the treatment is intermitted the gland enlarges and the cough returns. Pressure on the pneumogastric nerve from the enlarged thyroid is the cause of the cough.

Miss G. F——, twenty-seven years old. This is a case of cough from pressure of a neoplasm. The cough was of the imperfect kind and pretty constant; at first it was thought to be of pulmonary origin. Later events proved it to be due to pressure from œsophageal cancer. The cough was the earliest symptom complained of.

The question of therapeutics in these cases of reflex cough may be dismissed with a word. It depends entirely upon the diagnosis. That is the difficult and most important part. Once the diagnosis is accurately made the treatment is readily adapted to the individual case.

## A CASE OF TRAUMATIC NEUROSIS WITH HEMORRHAGES FROM THE PHARYNX.

By EDWARD von ADELUNG, M.D.,

OAKLAND, CAL.,

LECTURER ON DISEASES OF THE NERVOUS SYSTEM, AND FIRST ASSISTANT IN THE CLINIC FOR NERVOUS DISEASES, IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF CALIFORNIA.

On the evening of April 3, 1898, a railroad train on which Mrs. G. S—— was a passenger started before she had time to alight. The brakeman took hold of her left arm while she was still three car-steps from the ground, and, in spite of her protests, pulled her off, causing her to fall. She struck on her knees and right arm, her body proper probably not touching the ground. She suffered a psychical as well as a physical shock. She was dazed, but in a few seconds arose, and, with the assistance of friends, walked home, a distance of about four blocks.

Immediately on arising she felt a "gush" of fluid from the vagina, which after reaching home she discovered was blood. It had soiled her underclothing and her stockings. She had ceased to menstruate four days previously.

That night she did not undress and did not sleep, but paced the floor almost constantly. Toward morning she began to have a good deal of pain, mainly in her back. The right arm had been paining since the fall. For several days subsequently she took no food.

But before giving the further development of symptoms I wish to call attention to her family history and to her previous history. Her father is not an alcoholic nor is he of a neurotic temperament, he has always been a healthy man, and is still hale at seventy-four. Her mother was apparently a very healthy woman, but died suddenly while alone at home, of some "brain trouble." She appeared well until her death and had never been nervous or hysterical. Her sister is well and not of a nervous temperament None of her family shows signs of a neuropathic constitution; and, aside from her mother, all are living and in excellent health.

Mrs. G. S—— is a well-preserved, pleasant, bright woman, thirty-six years of age. She married young, and was never nervous or hysterical even during puberty. She has had one miscarriage, during the fifth month, due either to overexertion while travelling, or to medicines administered. The second fœtus was removed by instruments, also during the fifth month, on account of persistent vomiting. Both fœtuses were well formed and alive. The third and last pregnancy brought her a boy, now about eight years old, healthy and robust. She and her friends are positive that she was never in any sense a nervous, excitable, or hysterical woman before the accident. As an instance of her sound temperament they relate how she barred the door of her house some years ago while her husband held it shut in the face of a mob of men who came to eject them from their premises. A charge from a shotgun penetrated the door and cut her sleeve, but she remained at her husband's side and they succeeded in excluding the intruders. For a brief period

subsequently she carried a revolver for self-protection until the difficulties were adjusted.

She was then, up to the date of the fall, a cool, deliberate, intelligent lady, not given to worry, entirely happy and contented, and, aside from her miscarriages and the confinement with her boy, was never seriously ill. Previous to her confinement she had occasional sick headaches, which were always dissipated by vomiting. They have not returned since the birth of her boy. It can safely be assumed that she was an exceptionally well woman during the eight years just preceding the fall. Her menstrual periods were painless and regular in all particulars; she did not suffer from headaches, had no cough, her bowels and digestion were in normal condition; she was a communicative and sociable companion and a cheerful wife.

On the afternoon succeeding the accident I found her in her room dressed, and pacing up and down the floor aimlessly. She supported her back with one hand, and with the other grasped pieces of furniture to assist herself as she moved about. She complained of much pain in the back and right arm, and said she was very "sick all over." When asked to seat herself she replied that she could not sit down, she was too nervous. She was very restless, and she spoke in a slow, hesitating manner, often leaving her sentences unfinished.

After considerable urging she went to bed. The only external sign of injury was a slight bruise—discoloration above the right knee. The womb was in good position, and I could discover nothing abnormal with the ovaries or other sexual organs. (Several months later repeated speculum and bimanual examinations failed to reveal any disease except a slight cervical catarrh.) I found disordered sensation and weakness of the muscles all over the body, but both were more pronounced on the right side. The spinal region was very tender, and there was some stiffness in the muscles of the back and of the right limbs. The right arm and leg were colder than the left, both subjectively and objectively. Pain was caused by pressing on the tendons at the bends of the elbow and knee on the right side.

On the evening of the same day she had an hysterical attack; she was much excited emotionally and physically, and during the attack there was a tonic contraction of the flexors and pronators of the right arm and hand, so that the arm and hand were flexed, and the forearm and hand hyperpronated. The flexion of the fourth and fifth fingers was greater than that of the others.

Since that day, now nearly a year, the following symptoms have been present, varying very much in intensity at different times:

Disposition: While she was formerly a cheerful, chatty, patient wife, not given to noticing trifles, and not taking trouble seriously, she has, since the accident, become serious, irritable, easily angered and annoyed, at times morose and despondent; she is no longer talkative, but prefers to sit alone much of the time.

Mental concentration: Since the accident she has been unable to fix her attention on a subject for any length of time. This unfits her for mental work of all kinds. It makes reading, writing, and such occupations disagreeable if not impossible. When she persists in reading she fails to understand what she reads.

Energy: She has very little energy, either physical or mental. She has lost her former ambition and spirit.

Speech: During the first few days after the accident she spoke in the manner described. It seemed to be a reflection of the imperfections in her mental operations; speech was slow and sentences were unfinished because thoughts were slow and incomplete. For months now I have been unable to detect any defect of speech, but she states that she cannot speak so fluently and rapidly as formerly, and that occasionally she stutters a little.

Insomnia: Her sleep is broken, and fails to rest or refresh her. She was formerly a good sleeper.

Gait: She frequently staggers somewhat, but at times there is nothing to remark except a slowness and evident care in walking. During most of the first two months she was unable to support her weight in walking. She was abed most of that time.

Muscular power: Roughly tested, it was found markedly weakened in the right limbs. Her general strength was also much less than it formerly was. Walking fatigued her quickly, so that she could not accomplish ordinary distances.

Muscular tension was usually complained of as stiffness or as a "drawing in the cords." Her legs feel stiff and clumsy when she walks.

Muscular spasms occurred in combination with the hysterical attacks described. Sometimes during the first few months all four limbs were affected, only the right side, however, to a marked degree. Later the feet and the left arm escaped.

Muscular twitchings occurred during the nervous excitation which preceded and followed the hysterical paroxysms. Single muscles contracted in clonic spasms.

Ptosis: The patient complained of a "laziness" of the right upper eyelid. After closing the eyes the lid was slow in opening.

Astasia: Weakness in the knees was occasionally so great that the patient fell to the floor. This occurred once at four o'clock in the night, some eight months after the accident. She could not get up, and lay some minutes on the porch until others in the house, attracted by the noise, came and assisted her back to bed.

Reflexes: The patellar reflex was sensitive, such as is found in neurasthenia or hysteria. The jaw jerk was present. Tickling the soles caused the left foot to be retracted, but not the right.

Pain: This was located mainly in the back and the right arm. There was also during the last few months much pain beneath the left nipple, such as occurs in hysteria. For a few weeks after the accident pain was also suffered in the left hypochondriac region and in the lumbar region. There has been pretty constant pain in the region of the sixth and seventh dorsal vertebræ.

Spinal tenderness: This was marked during the first two months, and was then distributed in the lower cervical, the whole dorsal, and the upper lumbar regions. Later the sensitiveness decreased much, and is now almost confined to the seventh cervical, and the first, third, sixth, and seventh dorsal vertebræ. For months she could not wear corsets, and now she cannot wear them all day long.

Abdominal tenderness: This was marked for a week or two following the accident. Pressure on the left hypochondriac or on the left ovarian region caused much pain.

Headache: This has not been a prominent symptom, but she has suffered on many days a dull, steady headache, something that was rarely experienced previous to the accident.

Vertigo was slight. A few attacks occurred during June.

Girdle sensation: The girdle sensation was transient, distinct, and infrequent; it was noted soon after the accident and two or three times after long intervals. It moved from its location below the costal margins to the head.

Pressure sensation: A feeling of pressure on the vertex distressed the patient at times.

Cold spots: A subjective sensation of cold was located mainly on the back of the head and in the upper spinal region. A sensation of lowered temperature affecting the whole right side, except the head, was confirmed objectively on many occasions.

Tingling and numbness have been very marked at times. The skin on the right side "feels like leather." There is a bluntness of sensation to touch, temperature, and pain on all of the right half of the body except the head. This partial hemianæsthesia has been quite persistent, both subjectively and objectively.

Trophic symptoms: There has been some loss of weight. A considerable loss of hair, mainly from the right side of the head, was complained of by the patient within a week after the accident and noted later by friends. Her hair is also much drier than formerly. In February wheals, preceded by burning pain, developed on the left side of the forehead and scalp, and lasted a week or ten days. Tache cérébrale was noted on the back soon after the accident.

The pulse and temperature were constantly normal, but were not observed during the first week.

The appetite was entirely absent for over a week, and is still much below her normal. For some days the patient ate nothing, and had a decided aversion for water. Constipation has been persistent for some months. At first there was either retention or diminished secretion of urine; and at later periods she had attacks of frequent micturition accompanied by vesical pain, which lasted only a day or two at a time.

Menstruation: In June and August the menstrual periods were missed. The other periods were irregular as to time and quantity. Each period is preceded by a week of dejection and nervousness, and pain is suffered during the flow.

Hysterical paroxysms occurred very frequently during the first months and then decreased in frequency. They were always preceded and followed by hours of nervous excitement. They were marked by emotional and physical excitement and were accompanied by tonic spasm of all the limbs during the first weeks, yet always more marked on the right side. Later only the right arm and hand were affected. The duration was less than two hours, but the whole attack of nervousness lasted from a few hours to a couple of days. When the muscular spasm relaxed, the patient was unable to use the affected limb or limbs for ten or fifteen minutes.

Unilateral contraction of the field of vision: An examination of the eyes by Dr. H. G. Thomas showed normal fundi. The field of vision of the right eye was contracted from ten to twenty degrees in all directions. The field of vision of the left eye was absolutely normal. Color blindness was not present.

Sexual desire: Previous to the accident she had always demanded considerable attention from her husband. Immediately succeeding the accident this desire was much increased; but in a short time it rapidly decreased until all desire was gone.

Pharyngeal hemorrhages: These began in the latter part of April and have continued to date. At first she had two or three a week; once or twice she had two in one day; during the last months they have been less frequent, occurring about once a fortnight. Immediately preceding the hemorrhage she experiences an indescribable sensation (not nausea) beginning in the epigastrium and rapidly spreading over the whole body as the hemorrhage occurs. She does not lose consciousness, but gets very weak, limp, so that she is always obliged to lie down. On several occasions she had to lie down on the floor. The blood fills her mouth and flows out rapidly to the amount of about one or two ounces. The blood is ejected into a handkerchief, a handy receptacle, or, these failing, on to the floor. The saliva is tinged for a little while subsequently. The whole attack, including the duration of the weakness, lasts ten or fifteen minutes; she then regains her feet and is as well as usual. The attacks have occurred under various circumstances—while alone, while in company, at the dinner-table, sitting, standing, or lying down. She says, however, that they occur oftener while she is leaning over. Vicarious menstruation was excluded. The blood is rather bright red, alkaline, and there is no nausea nor vomiting, nor indeed gastric trouble of any kind. The lungs are perfectly sound; the attack is neither preceded, accompanied, nor followed by coughing. There is no trouble in the nasal cavity, and none of the blood ever escapes by the nose, although the head is usually thrown forward. There are no polypi, adenoids or other growths, or ulcerations in the nose or pharynx. I found a few isolated enlarged blood-vessels on the pillars of the pharynx; but by using mirrors a much dilated and engorged plexus of veins was discovered on the base of the tongue. I am satisfied that it is from these engorged veins that the blood flows. The plexus is located in the median line, well down on the base of the tongue, and is of a bluish color.

The features of special interest in this case are as follows: The slight degree of physical shock which, combined with the psychical shock, was sufficient to cause the disease. The patient's previous history and that of her family are not neuropathic, which goes to support those who claim that traumatic neuroses occur in persons who are not of the neurotic temperament. The immediate development of some of the prominent symptoms, and the delayed development of others. The one uterine hemorrhage which occurred immediately after the accident. The frequent periodic pharyngeal hemorrhages which developed later. The marked unilateral contraction of the field of vision.

Malingering and exaggeration were readily excluded in this case, although within a fortnight after the accident a lawyer was consulted and a suit was prosecuted, which occupied the month of February, and resulted in a verdict for the plaintiff.

The explanation of the pharyngeal hemorrhages is an inviting field for speculation. If we accept the view advanced by some authors, that the symptoms of traumatic neurosis are a combination of the symptoms of neurasthenia, hysteria, and hypochondria, these hemorrhages might be classed with those rare cases of genuine hemorrhage due to hysteria. Cases of "pulmonary hysteria," or of hysterical pulmonary hemorrhages, have been reported by Camuset,[1] Debove,[2] Championnière,[3] Legrand du Saulle,[4] and Roulin.[5] In this case the facts that each hemorrhage is preceded by an epigastric prodrome, and that the nervous accompaniment of the hemorrhage is marked and constant, would indicate a probable nervous origin. Accepting the theory, indorsed by Oppenheim, that in this disease the nerve centres suffer some molecular change, and supposing such a change in the vasomotor centres, it might not be difficult to account for the dilated condition of the blood-vessels at the base of the tongue, and also for their occasional rupture. The intermittent lowered surface temperature of the right side could then be explained in a similar manner.

This view seems to have had the support of Vulpian, who states "that it would be legitimate to connect the

hemorrhages with a paralysis which supervenes during the period of reaction at the moment when, following a more or less intense and prolonged excitation, there occurs a weakness of the excito-motor power of the spinal cord, the activity of the centres which control the tone of the vessels being suspended. More often, it is true, these disturbances of vascular contractility produce only local hyperæmia or anæmia, alternating flushing and blanching of the face, tendency to cold hands and feet, the phenomenon of 'dead finger,' etc. But supposing an increased degree of excitement, or even a vascular paralysis, one easily comprehends how genuine hemorrhages could occur."[1]

Laurent[2] reports three cases of pulmonary hemorrhage in men, which he describes under the title, pulmonary hysteria. He calls attention to the fact that while a few cases of pulmonary hysteria in women have been reported, his cases of the disease are unique as occurring in men. His three cases were all in criminals of a strong neuropathic diathesis.

The first patient was also an epileptic who began to have hæmoptysis five days after receiving a knife wound below the angle of the left scapula. Fifteen days later the man was supposed to be entirely healed both of his wound and of his hemorrhages, when an epileptic fit occurred, accompanied by hæmoptysis. The fits, which had for some time been infrequent, now recurred frequently and were always accompanied by hæmoptysis. Very curious is the description of how the blood was spurted against the wall near the man's bed, until the whole partition became blood-smeared to a height of some six and a half feet. The quantity lost during each fit was about half a glass.

The second man had no cough nor did he spit. One day he felt a severe pain in the region of the false ribs on the left side, followed by a sense of suffocation, and then without effort the hemorrhage occurred. The amount of blood lost each time was about a litre.

The third patient was kicked and bruised by police officers who arrested him. He was of a nervous and irritable character. His hæmoptysis was preceded by a very distressing dyspnœa. The amount of blood lost each time was "considerable."

It will be observed that in two of the cases a traumatism preceded the occurrence of hæmoptysis, and that other nervous symptoms were present.

From those three cases, whose histories I have not attempted to detail, Laurent deduced the following features of the disease: Hemorrhages may be the principal symptom or only a secondary feature of the disease. Usually the hemorrhages begin suddenly without apparent cause; sometimes they are preceded by a trauma or by an emotional shock. The amount of blood lost is usually greater than is common in pulmonary tuberculosis. It is not rare to see the hemorrhages occur periodically. In some cases the hemorrhage occurs during or succeeding an hysterical paroxysm, but in other cases the hemorrhages occur as is common in pulmonary tuberculosis. The blood is usually red, fluid, rarely clotted, and varies in amount from tinted sputum to a litre. The hemorrhages may occur daily, weekly, or monthly, more or less regularly. On physical examination of the chest signs of disease are found to be absent, or slight and evanescent. Two stigmata of the disease that he regards as very important are hyperæsthetic points and the general symptoms. The former are located principally in the intercostal spaces, in the supra- and infraclavicular fossæ, and in the supra- and infraspinous fossæ. The slightest pressure on those areas causes great pain. The temperature is always normal. In spite of loss of blood, even in considerable quantities, the patients do not grow thin and their general condition is hardly altered.

In closing the history of my patient, I should state that nearly all her symptoms varied much in intensity from week to week. There were days, more frequent latterly, when she could walk quite well; some days when she was cheerful and optimistic; and there were times when she ate well. The hemianæsthesia, however, was quite constant, and the hemorrhages persisted. The amount of blood lost was variable, being on some occasions less than half an ounce. During the first two months she improved very rapidly, then slowly but perceptibly.

I am indebted to Dr. Leo Newmark for assistance in the study of the case, and to Dr. H. G. Thomas for valuable aid in locating the source of the hemorrhages.

## Progress of Medical Science.

**Successful Extirpation of a Rapidly Increasing Arterio-venous Aneurism of the Femoral Vessels.**—Murray and Page (*Lancet*, June 3, 1899) report the case of a muscular, well-developed, steady-living man twenty-six years old, who presented himself with a pulsating tumor situated about the middle of the right thigh. Some eight years previously a sharp pocket-knife which he was using with his left hand entered the right thigh and caused profuse hemorrhage. The man was able to walk to his home, a short distance away, where the wound was dressed with a pad of cotton-wool secured by means of an elastic bandage, and in a few days it was healed. Pulsation was immediately noticed, and swelling shortly afterward. The latter gradually increased in size, and for a few months it had enlarged rapidly. The man had continued his work as a clerk, and had been active physically. Latterly, however, the rapid enlargement of the swelling and the increased pulsation and thrill in the limb had caused interference with sleep, and had rendered the man apprehensive that the swelling would burst. The right leg ached a good deal, and was often numb. On examination a pulsating swelling as large as a fist was found just under the skin covering the site of Hunter's canal. In it could be heard and felt the thrill characteristic of communication between an artery and a vein. There was no œdema of the leg, and no enlarged superficial veins were visible. The thrill was transmitted along the course of the vessels of the leg to the sole of the foot and to the iliac arteries. Both limbs were equally well nourished. An elastic tourniquet being first placed around the leg immediately below the knee, a second was placed around the thigh as high up as possible, and an incision about eight inches long was made over the course of the femoral vessels, and the sac was exposed. This was with difficulty dissected free from the muscles, to which it was pretty closely adherent. The artery and vein, both much dilated, but otherwise apparently healthy, were tied with catgut ligatures three-quarters of an inch above their communication with the sac. A quarter of an inch below the point of communication the artery was found to be smaller than natural and the vein to be much larger. Both were secured with catgut ligatures. The sac was then dissected out and, together with the attached portions of the artery and the vein, was removed. A considerable number of vessels had to be tied. A strip of iodoform gauze was introduced as a drain, and the wound closed with silkworm gut. The operation lasted a little more than an hour. The sac contained liquid and coagulated blood. In some places it was exceedingly thin, while in others it was

thickly coated with calcareous material. Two days later the circulation in the foot was excellent. A good deal of bloody serum had drained from the wound, but the gauze was now removed. The stitches were taken out on the fifth day, and on the fourteenth the patient was allowed to sit up in bed, and he was dismissed cured on the twenty-second day.

**Successful Removal of Subclavian Aneurism Thirty-Eight Days after Ligature.** — Allingham (*Lancet*, June 3, 1899) has reported the case of a seaman, twenty-five years old, who three years before coming under observation had noticed a swelling above the right clavicle, which increased gradually in size, the increase being especially marked during the preceding twelve months and being associated with occasional attacks of numbness and severe aching pain in the right upper extremity. The pain had at first occurred only at intervals, but it subsequently became continuous, without being accompanied at any time by swelling below the tumor. The patient's general health had always been good, and syphilis was denied. On examination a pulsatile, expansile swelling, about the size of a tangerine orange, was found in the right supraclavicular region, filling the interval between the sternomastoid and trapezius muscles. A characteristic systolic bruit was audible, with delay and diminution of the right radial pulse. There was some slight tenderness on pressure over the tumor, but otherwise there was no symptom except the pain passing down the inner side of the arm and forearm to the little finger. On consultation it was decided to ligate the subclavian artery on the cardiac side of the tumor. Accordingly, a V-shaped incision was made, one branch of which passed down the anterior border of the sternomastoid, and the other along the clavicle. The flap of skin was turned up, the sternomastoid muscle divided, the first part of the subclavian artery exposed, and a kangaroo tendon passed around the vessel immediately external to the origin of the vertebral and just to the inner border of the scalenus anticus. Recovery from the operation was complete, and at no time was there any indication of secondary hemorrhage. No pulsation was felt in the tumor or in the brachial or radial artery. After three days some slight beating was detected in the aneurism, and this continued, although the sac, meanwhile, grew distinctly smaller and harder. After two weeks, as the pulsation was still decided, the patient was again anæsthetized. The tumor, although pulsating, was found not to expand with the beat of the heart, and it was therefore considered advisable to watch its progress further before attempting more radical measures. Eleven days later it was noted that the aneurism was increasing in an upward direction, and that there was more pulsation, which was both visible and palpable. The radical operation was performed thirty-eight days after the primary one. The whole length of the clavicle was exposed by a transverse incision, and in order to get plenty of room to deal with the aneurism a vertical incision was made at right angles to the transverse incision. Then large skin-flaps were reflected, and the greater part of the clavicle was resected, leaving only the two extremities. Careful dissection revealed the aneurism, springing from the upper and anterior aspect of the vessel in its third portion. With great care the cellular tissue, the nerves, and the vessels surrounding the aneurism were dissected off the sac. Then the axillary artery was sought for, ligated with silk, and divided on the distal side of the tumor. This procedure allowed the aneurism to be freed from the first rib and turned upward, and thus to bring into view the second part of the subclavian artery on the proximal side of the aneurism. This part of the artery was ligated with silk, and the aneurism was cut away. During the dissection the transversalis colli artery was divided as it crossed the tumor, as well as some few fibres from the brachial plexus passing into the pectoralis major muscle. The lower part of the brachial plexus was adherent to the upper part of the tumor and had to be dissected off it. Some difficulty was experienced in separating the subclavian vein, which received a slight tear, necessitating a lateral ligature. The amount of blood lost was quite inconsiderable, notwithstanding the number of vessels divided, owing to the establishment of so free a collateral circulation. The operation occupied two hours. The after-history was unimportant, the large wound healing after some slight sloughing of the skin. A section of the aneurism showed that its cavity was largely occupied by firm clot, the blood passing into it from the subclavian, which was partly patent, and out posteriorly by way of what appeared to be the profunda cervicis. In shape it resembled a pear, with the stalk external and the base upward. The axillary artery, so far as it was exposed in the wound, was found to be obliterated. On examination of the arm four weeks after the operation, pulsation was found present in the brachial artery, best marked in the antecubital space, and also in the radial at the wrist. The ulnar was not felt. The hand and fingers were somewhat pallid and colder than those of the opposite limb. This condition, however, underwent progressive improvement.

**Intrauterine Vaporization.**—After considerable personal observation in conjunction with a survey of the literature of the subject, Brothers (*New York Medical Journal*, May 13, 1899) concludes that as a hæmostatic intrauterine vaporization, or vapo-cauterization, has been employed most successfully in cases of non-malignant, post-climacteric uterine hemorrhage. It has proved curative in the various irregular bleedings encountered in connection with catarrhal, fungoid, or hemorrhagic endometritis. It acts as a palliative measure in certain cases of fibroid tumor or inoperable carcinoma associated with hemorrhages. As a caustic, vapo-cauterization can be relied upon to destroy the mucous lining of the uterus, even to the extent of obliterating the uterine canal. As a bactericide the procedure may be employed in cases of gonorrhœal or septic puerperal endometritis. The uterus subjected to vapo-cauterization and subsequently removed by excision has, when examined bacteriologically, been found sterile. Vapo-cauterization has frequently been employed successfully to reduce the bulk of the subinvoluted uterus, and in some cases of chronic suppurating abdominal fistulæ which had resisted other means of treatment.

**Symptoms Following Lumbar Puncture in Tabes Dorsalis.**—Having observed relief of intracranial pressure from lumbar puncture in cases of general paresis, together with subsequent improvement in the ataxia in several cases, Babcock (*American Journal of Insanity*, vol. lv., No. 4) was led to the experimental trial of the same procedure in cases of tabes dorsalis. The main indication for puncture in paresis is heightened intracranial pressure, which, however, is not often present in tabes. Of three cases of the latter in which this procedure was employed, only one presented evidence of an excess of cerebro-spinal fluid prior to puncture; in the second the operation was performed to ascertain if the symptoms developing after puncture would establish the diagnosis; while in the third puncture was entirely experimental. In the first of these cases there was marked improvement in the ataxia. In the second, in which the diagnosis was obscured by the existence of multiple fractures, and by the mental condition of the patient, classic symptoms of tabes developed after puncture, subse-

quently subsiding in part, but without improvement in the ataxia. In the third case the result was entirely negative.

**Appendicitis Complicating Pregnancy.**—In a communication presented recently to the Brooklyn Gynæcological Society, Gordon (*Brooklyn Medical Journal*, June, 1899) expressed the opinion that it is the duty of the medical attendant of a woman who is subject to pregnancy, and who gives a history of recurrent appendicitis, to advise the removal of the appendix, in order that she may escape the complication of appendicitis and pregnancy. An operation should be urged in all cases when the diagnosis is not in doubt, and more especially in the early weeks of gestation, as the patient might recover from one attack and the trouble recur at a later stage with increased danger to both mother and child. Pregnancy does not contraindicate operation. Success depends largely upon early diagnosis and treatment.

**Leucocytosis Associated with Convulsions.**—As the result of observations made on the blood of seven patients suffering from convulsive seizures during the progress of general paralysis, senile dementia, terminal dementia, katatonia, and puerperal eclampsia, Burrows (*American Journal of the Medical Sciences*, May, 1899) found that there is a leucocytosis associated with convulsions, not only in general paralysis but in various other diseases as well, and that the leucocytosis bears a relation to the severity of the seizure. It was further learned that this leucocytosis is due in part to the muscular activity manifested during the convulsion, a part that, owing to its physiological character and its short duration, has been shown to be superimposed upon a pathological leucocytosis of longer duration.

**Tuberculoma of the Cerebellum.**—Wolf (*Archiv für Kinderheilkunde*, B. 26, H. v., vi.) reports a case of large solitary tuberculous tumor of the cerebellum, and tabulates twenty-one additional cases collected from the literature. In eight cases the growth was situated in the right hemisphere; in four, in the left; in four, in the vermiform process and both hemispheres; in two, in the vermiform process; in one, the vermiform process and the left hemisphere; in one, in the right cerebellar peduncle; and in one, in the right hemisphere and cerebellar peduncle. From a study of these cases it is concluded that tubercles may be present in the cerebellum without giving rise to morbid manifestations. Therefore it is never possible to determine precisely the duration of the disease in the individual case, as the process may pursue a latent course until the appearance of the first symptoms. In the majority of cases tuberculosis of other organs is found in addition to that of the cerebellum. Among the most common symptoms of tuberculosis of the cerebellum are staggering gait, variation in the size of the pupils, nystagmus, strabismus, headache, optic neuritis, convulsions, opisthotonos, but these occur in no fixed order or arrangement, and they justify no definite localizing conclusions. Previous clinical experience indicates that the cerebellum is a homogeneous organ, and that its individual parts do not possess various functions. Lumbar puncture may be practised in cases of tuberculosis of the cerebellum without fear of injurious results. In fact, in some cases relief is afforded thereby.

**Inhibition.**—Meltzer (*New York Medical Journal*, May 20, 27, 1899) reaches the following fundamental conclusions with regard to inhibition: (1) Inhibition extends as far as the existence of irritability, and is an integral part of it. All irritable tissues of the living body respond to a stimulus with a specific activity, as well as with an inhibition of this activity; the actual effect of a stimulation is always only a resultant of the two opposing factors, but mostly, perhaps, with a greater leaning toward one or the other, according to external circumstances. Neither the impulse of activity nor that of inhibition is wiped out; they often run out their course in an imperceptible manner. (2) All the actual phenomena of life are not the pure manifestations of one of these factors, but are the resultants of the two antagonistic forces; there is no absolute rest in a living part, and there is no action without any admixture of inhibition. The state of life in each part of the body depends upon the general relations between the two antagonistic forces in the entire body, and upon the special relations existing in this special part. All admitted biological laws that have been formulated under the presupposition that they were being derived from a study of the behavior of the pure activity will have to be revised. (3) In the peripheral, as well as in the central, organs activity and inhibiton are apparently separately accessible by special nerve-fibres, of which the government of the body is making use in such a purposeful manner as to cause a required degree of inhibition of a part, the antagonist of which is ordered to action.

**Hysteria Simulating Acute Visceral Inflammation.**—Dr. William H. Robey, Jr. (*Boston Medical and Surgical Journal*, May 11th) says that despite the increased knowledge of the abdominal cavity and the improved methods of examination, the differential diagnosis between real and simulated pathological conditions is attended with great difficulty, and in view of this fact he reports a few cases, from which he draws the following conclusions: (1) The importance of regarding each case as one of organic disease until proved to the contrary. (2) With persistence in the localization of pain and tenderness; (*a*) early rectal or vaginal examination, (*b*) early consultation. (3) Laparotomy in doubtful cases. As Byrom Bramwell says: "The friends of the patient will more readily forgive a laparotomy which finds the viscera in normal condition than a diagnosis of hysteria followed in a few days by death."

**Recurring Appendicitis.**—Dr. von Mayer (*Gazette Médicale Belge*, April 20th) raises the question as to whether we can draw a conclusion between two attacks of appendicitis from the subjective state of the patient as to the probable state of the appendix. In order to answer his question he has collected seventy-five cases, operated upon between attacks, and has compared the objective state of the organ with the subjective condition of the patient, and from these data Dr. Mayer concludes: (1) That the subjective state of the patient is not an adequate guide as to the state of the appendix. (2) The number of attacks and the degree of suffering occasioned are not always reliable indications as to the state of the appendix. There is no sure relation between these two factors. A brief experience suffices to teach us that the mildness of previous attacks is no guarantee against recurrence, or against the gravity of succeeding attacks. (3) The disappearance of the greater number of adhesions and the arrangement of those remaining teach us, after very slight experience in operating, how little we can count on these adhesions in determining future attacks; the pyogenic organisms are present which may induce a subsequent outbreak. (4) To declare a patient absolutely cured and free from the danger of future attacks while the appendix remains in the body is absurd, when we have so many instances of an appendicitis recurring after two, ten, twenty, and even forty years. (5) When a patient suffers pain, operation is imperative, for it is impossible for a man to make his living if the least effort occasions pain.

# MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, August 5, 1899.

## EXCISION OF THE CERVICAL SYMPATHETIC.

WE are compelled to admit that up to the present time the treatment of epilepsy, Graves' disease, and other troubles in which the sympathetic system seems to have an important rôle, is in an unsatisfactory condition. The exact pathology of Graves' or Basedow's disease we do not know, and we are constantly coming across facts in our study of epilepsy which force us to conclude that we do not know so much on that subject as we might, and it is our lack of knowledge which makes the treatment of these conditions so uncertain and empirical. We are practically certain that very many of the symptoms of Graves' disease are due, fundamentally, to some alteration in sympathetic (and vasomotor) control, but we can only guess at the nature of this alteration. In epilepsy the part played by the sympathetic seems less constant and more irregular in its manifestations than in the case of Graves' disease, but it is undoubtedly important.

Jonnesco, of Bucharest, has twice recently (1897–99) in communications to the *Centralblatt für Chirurgie* given us the results of his experience in treating epilepsy and exophthalmic goitre in a new and interesting way. He has acted on the assumption that some abnormal action on the part of the cervical sympathetic is responsible for a large proportion of the symptoms of these diseases, and has consequently attacked them by removing the ganglia and connecting filaments on one or both sides. In his last communication this writer gives us some results which are encouraging. He has operated upon over forty cases of epilepsy, and has been able to follow carefully nineteen of them, among which ten remained free from convulsions for periods varying from six months to two years, the limit of observation. Six more patients were much improved, and only two put down as unimproved. Jonnesco has also operated upon ten cases of Graves' disease, of which he classes six as cured and four as improved, and in all the beneficial effects were immediate. Good results were also claimed in several cases of glaucoma, in which partial or complete resection was done.

If we consider that the main symptoms of epilepsy are due to a disturbed and perverted cortical circulation, with all the trophic and metabolic irregularities which such circulatory changes would naturally produce, we may explain the beneficial results of extirpation of the cervical sympathetic system, by noting the physiological effects of the removal of these nerves. There is prompt and marked cerebral congestion, and any small local areas of congestion or anæmia are washed away at once, and there is further a marked increase in the metabolism of the brain-cells. If the epilepsy was of peripheral origin, say from some visceral cause, the path to the cerebrum is cut off by the operation and its success explained in part in that way. In the case of exophthalmic goitre, the operation seems to act by freeing the heart from some abnormal sympathetic control, at the same time that it frees the vessels of the head from a constantly acting but occasionally irregular vasoconstrictor influence. Jonnesco claims that the exophthalmos disappears at once, and that there is a change in the thyroid gland which results in a sclerosis, and that the patients feel better at once. The operation does not present any particular surgical difficulties or dangers, and should give no mortality. We should think that the benefits of this operation ought to be more manifest in epilepsy, in those cases called idiopathic, and not in the traumatic variety in which the convulsion starts from some more or less gross injury to the cerebral cortex acting continuously as a serious disturber of local circulation, and consequently as the starting-point of the convulsion. There is room for further investigation upon this subject, and we hope to see some American experiences recorded soon.

## PHOSPHORUS POISONING IN MATCH-MAKING.

EVER since the science-loving perseverance of Dr. Charles Marc Sauria resulted in the great discovery that, by combining phosphorus with such an explosive mixture as potassium chlorate and sulphur, matches could be made, there has been more or less danger resulting from the process of their production. At times the evil consequences to those engaged in manufacturing these most useful little contrivances have been so great that investigations have been instituted and legislation sought. Such an investigation of the question of the prevalence and prevention of bone necrosis, or what they seem fond of designating "phossy jaw," was recently undertaken by the British government, and the report would tend to show that the condition, while somewhat prevalent, is in a great measure preventable.

Professor Thorpe, of the government laboratory, has shown the distinctions to be made between yellow and red phosphorous, the products of oxidation of the first being phosphorous oxide and phosphoric oxide, and this alone oxidizes at the ordinary atmospheric temperature. The glow, he thinks, depends upon ozone formation which always accompanies the process. A practical suggestion made by this gentleman is that the atmosphere of the factory be impregnated with the fumes of oil of turpentine.

Where proper hygienic rules are insisted upon, the

dangers are, according to the report of Dr. Oliver, another commissioner, reduced to a minimum.

In some Continental factories it is forbidden to take food or drink in the workshops. Those who wish a light meal are sent to a special dining-room after (1) leaving their working-clothes in the cloak-room, (2) washing their hands in soft soap and water, and (3) washing the mouth with a specially prepared solution.

Dr. George Cunningham, senior dental surgeon to the London Hospital, who is well known in this country, having been graduated at Harvard and practised his profession for a time in this city, is the third member of the committee to report. Naturally his investigations have gone largely into the nature of caries of the teeth and bone necrosis following this decay, and he finds the greatest amount of injury results in those factories which have no provision for teeth inspection and where hygienic conditions are lacking. He quotes Smale to the effect that phosphorus necrosis can originate only under the following circumstances: (1) When dental caries has exposed the pulp of a tooth; (2) during the healing process after tooth extraction; and (3) during the time there is some lesion of the gum. For these reasons the recommendation is made that those whose teeth are defective should be excluded by primary and subsequently periodic medical and dental examinations, and that a mouth wash for systematic use should be provided. On the whole the reports, which fill an illustrated volume of two hundred and thirty-six pages, are of decided interest and importance to all those who have to do with match-makers. The safety match would seem to be doubly well named, from the fact that its manufacture is unattended with equal dangers; but the desideratum of a red phosphorus article which can be ignited elsewhere than on its own box-lid, and which can be manufactured at a profit, appears difficult of accomplishment.

## SPINAL ANÆSTHESIA, AN AMERICAN DISCOVERY.

In a recent issue, we adverted to Beer's[1] undertakings in the sphere of spinal anæsthesia. Since the publication of our commentary, our attention has been drawn to the fact that researches essentially identical were conducted and published in full by an American neurologist, fourteen years ago.

In 1885, Dr. J. Leonard Corning, of New York, caused insensibility in the parts supplied by the sensory nerves, issuing from the lower segments of the spinal cord, by means of the injection of a three-per-cent. solution of cocaine into the space between the spinous processes of the eleventh and twelfth dorsal vertebræ. "I was led to this expedient," he wrote (we quote from Dr. Corning's original paper published in 1885[2]), "from a knowledge of the fact that in the human subject numerous small veins (venæ spinosæ) run down between the spinous processes of the vertebræ, and, entering the spinal canal, join the more considerable vessels of the plexus spinalis interna. From these theoretical considerations I reasoned that it was highly probable that if the anæsthetic was placed between the spinous processes of the vertebræ, it (the anæsthetic) would be rapidly absorbed by the minute ramifications of the veins referred to, and, being transported by the blood to the substance of the cord, would give rise to anæsthesia of the sensory and perhaps also of the motor tracts of the same." Dr. Corning's first experiment was upon a dog; his second upon a man. In both the injection of the anæsthetic was made between the spinous processes of the lower dorsal vertebræ; and in both the result was paræsthesia culminating in more or less profound anæsthesia of the lower extremities, as revealed by searching tests with the needle and the electric wire brush.

These researches, greatly elaborated in method, were again brought to the notice of the profession by Dr. Corning in an article "Further Contributions on Local Medication of the Spinal Cord," with cases, published in the MEDICAL RECORD of March 17, 1888. Also under the caption, "Irrigation of the Cauda Equina with Medicinal Fluids," Dr. Corning, in his book on "Pain,"[1] published five years ago, described a procedure by means of which the anæsthetic is deposited within the membranous coverings of the spinal cord. After a somewhat lengthy preamble, Corning goes on to state that, "the patient readily consenting, I decided therefore to try the efficacy of an injection composed of tinct. aconiti, gr. v.; cocainæ, gr. ss.; aquæ, ʒ i. The foregoing solution was deposited directly upon the cauda equina in the following manner: A small trocar, half an inch long, and of the diameter of a wax match, was first thrust through the skin between the second and third lumbar vertebræ. A long, fine, hollow needle, screwed to an ordinary hypodermic syringe, was then passed through the opening in the trocar and down through the soft tissues adjoining the ligamentum interspinosum, till the spinal canal was entered. The entire contents of the syringe were then emptied upon the fibres of the cauda equina. Impairment of sensibility, amounting in certain localities of the legs to complete anæsthesia, was observed shortly to follow this injection."

So much for spinal anæsthesia—an American discovery surely, thrice established by the verdict of recorded history.

## THE FEVER AT HAMPTON.

THE outbreak of yellow fever which was discovered some days ago at the Soldiers' Home in Hampton, Va., emphasizes the necessity of untiring watchfulness on the part of the guardians of public health, and draws renewed attention to the folly of trusting to quarantine alone for protection against infectious disease. There is always a possibility of a leak through the most rigid quarantine, as was shown when cholera appeared in New York Harbor in 1892, and if this possibility is forgotten there is a chance of mischief

[1] Deutsche Zeitschrift für Chirurgie, April, 1899.

[2] The New York Medical Journal, October 31, 1885. See also "Local Anæsthesia" p. 90 et seq. D. Appleton & Co. 1886.

[1] "Pain in its Neuro-Pathological, Diagnostic, Medico-Legal, and Neuro-Therapeutic Relations," by J. Leonard Corning, M.D. p. 247 et seq. Philadelphia: J. B. Lippincott & Co. 1894.

which will be all the more serious because of the carelessness engendered by the false sense of security.

Fortunately the fever has appeared in a place where it can be easily checked, and there is not the slightest cause to apprehend the occurrence of an epidemic at the Home. There will doubtless be a few more cases among those who were exposed before the nature of the disease was recognized, and possibly the contagion has been carried elsewhere by inmates of the Home who have gone to visit friends outside of the institution, but the occurrence of a few such cases should excite no alarm. The attention of the country is now awakened, and there is little fear that any case of yellow fever occurring anywhere during the next fortnight will fail of diagnosis. The danger is rather that many timid souls will be agitated to the verge of panic by cases of malaria or catarrhal jaundice mistaken by inexperienced physicians for yellow jack.

## News of the Week.

**New Quarters of the Health Department.** — The work of moving the various departments of the board of health to the new quarters at Fifty-fifth Street and Sixth Avenue is now nearly completed. The department of contagious diseases moved a few days ago. This department will, however, have a branch, to be known as the down-town station of the contagious diseases department in a house on Elm Street. Thousands of down-town children have to be vaccinated in order to comply with the board of health regulations before the schools open in the fall, and it is partly for this reason that it has been decided to establish the down-town station.

**Typhoid Fever in Flushing.**—The epidemic of typhoid fever at Flushing, in the Borough of Queens, continues. During July there were about thirty cases with a mortality of about twenty per cent. It was thought at first that the water-supply was at fault, but repeated examinations of the water have failed to show the presence of typhoid bacilli or to cause a suspicion of contamination with sewage. It is now suspected that the outbreak may have been caused by impure milk. An inquiry showed that seventeen of the patients at least were using milk supplied by one dealer. The board of health will make an investigation to ascertain the cause of the epidemic.

**The Lehigh Valley (Pa.) Medical Association.**—At the annual meeting of this association, held at Glen Summit on July 27th, the following officers were elected for the ensuing year: *President:* Dr. Israel Cleaver, of Reading; *Vice-Presidents*, Drs. C. P. Knapp, Wyoming, J. H. Halber, Pottsville, O. H. Sproul, Flemington, and A. A. Seen, Bangor; *Secretary*, Dr. Charles McIntire, of Easton; *Assistant Secretary*, Dr. W. P. Walker, South Bethlehem; *Treasurer*, Dr. Abraham Stout, Bethlehem.

**The Rocky Mountain Interstate Medical Association** was founded in Salt Lake City in July, 1897, with Dr. Charles Pinckney Hough as president and Dr. S. D. Hopkins, of Denver, corresponding secretary. The permanent organization was effected in Denver in July, 1898, when the temporary officers were re-elected to serve until after the first regular meeting of the society. This was held at Salt Lake City on July 25th and 26th of this year, when about thirty papers were read and discussed. The election of officers resulted in the choice of Dr. Charles K. Cole, of Helena, Mont., as president, and Dr. S. D. Hopkins, of Denver, as corresponding secretary. Membership in the association is drawn from Arizona, Colorado, Idaho, Montana, New Mexico, Utah, and Wyoming.

**A Yellow-Fever Outbreak at Home.**—Yellow fever has been discovered among the inmates of the Soldiers' Home at Hampton, Va. According to the official report of Dr. Wasdin of the Marine-Hospital service, early in July an old soldier entered the home for a short rest, and soon afterward appeared at the dispensary, where he informed the physician in charge that he was but recently from Santiago, via a transport to a northern port. He complained of dumb chills and fever, and was prescribed for. He mingled freely with the inmates of the home, and a short time ago disappeared. This is a possible cause for the outbreak, or at least there is as yet no other known cause. On July 21st and 22d eight or ten of the inmates of the home suffered from pronounced chills followed by a high fever, but no suspicion of the true nature of the disease was aroused until July 27th, when a death occurred, the man becoming distinctly yellow some time prior to death. On the same day another man died and he also turned quite yellow. Autopsies were held on both by the resident pathologist, and a diagnosis of yellow fever was made tentatively, a request being sent to Washington for an examination by a Marine-Hospital surgeon familiar with yellow fever. This was made by Dr. Wasdin, who confirmed the diagnosis. There are thirty-five hundred inmates of the home, and thirty-five of that number were ill during the last ten days of July. The Marine-Hospital service has taken charge of the institution and quarantined the members, and there is little apprehension that the disease will spread to any extent. Dr. Leonard Wood has conquered yellow fever in its home in Santiago twice, and it will be strange if the Marine-Hospital surgeons cannot repress an outbreak in a place where the germ is an exotic. It is true that the surgeons here have not the absolute power of the governor of Santiago, but all the other conditions are in their favor.

**Cancer Study.**—At a meeting of the British Cancer Society, it was resolved to send Mr. Arthur C. Duffey, M.B., to the United States to investigate what is being done in the way of cancer study in the Buffalo laboratory.

**The Smoke Nuisance.**—Fifty complaints have been received by the board of health against persons and corporations for violating the ordinances regarding the burning of soft coal. They will be brought before the grand jury, which has already found indictments against several of the greatest offenders.

Health inspectors have found more than three hundred violators in Greater New York, one of them being the city itself, which is burning soft coal at a pumping station on Long Island.

**The Plague in India.**—At Poonah, a city on the railroad from Bombay, where the plague is raging with unusual fury, there were two hundred and ten new cases and one hundred and seventy-seven deaths during the last week of July. In all there have been three hundred and one cases and two hundred and sixty-one deaths. Several Europeans have been attacked and some have died.

**Typhoid Fever** is prevailing in epidemic form at Lobtau in Prussia. Up to the end of July there had been about one hundred and eighty cases, most of them occurring during the latter half of the month.

**Osteopathy Declared Unlawful in Pennsylvania.**—The Medical Council of the State of Pennsylvania decided on May 24th that the practice of osteopathy within the State is illegal, and that those therein engaged are amenable to the law.

**The United States Hospital Ship "Relief"** arrived at Honolulu on July 22, eleven days out from Yokohama, and proceeded directly to San Francisco, after coaling, arriving there on August 1st. She had on board three hundred sick soldiers from Manila.

**The Queen's Eyesight.**—According to the London *Truth*, which does not always live up to its name, Queen Victoria, who was suffering with cataract, underwent a ten-weeks course of treatment for her eyes prescribed by Dr. Hermann Pagenstecher, a German oculist. The treatment is alleged to have been most successful, and to have obviated the necessity for an operation.

**Rabies in New York State.**—According to Commissioner Weiting of the State agricultural department, the worst outbreak of rabies reported in years is now raging in Erie County, where men, dogs, horses, and cows are suffering from the disease. Four of the victims are now under the Pasteur treatment in New York City.

**Men Wanted for the Hospital Corps.**—It is said that there have been few applicants for enlistment in the hospital corps in this city, although in general men for the new regiments for service in the Philippines have been enlisting at a satisfactory rate. The hospital corps will form an essential part of the new force to be sent to Manila. Applicants for service in this corps should present themselves to the attending surgeon, at the army building. Those who have had experience in nursing are most desired for this work.

**The American Electro-Therapeutic Association** will hold its ninth annual meeting at Washington, D. C., on September 19, 20, and 21, 1899, under the presidency of Dr. F. B. Bishop. Willard's Hotel has been chosen for the headquarters, and special rates have been made for all interested in this meeting. Many papers have been promised, and a successful scientific meeting is anticipated. There will be an exhibition of electro-therapeutic apparatus in Willard's Hall during the meeting of the association. Willard's Hall is well adapted for this purpose, as it not only adjoins the headquarters but communicates with it by a corridor; there is also a large entrance directly from the street. The committee also promises a pleasant social programme, including a reception by the President of the United States, an excursion to Mt. Vernon, Arlington, and Alexandria, and an evening visit to the Congressional Library. Provisions have also been made to visit the War, State and Navy departments, the United States Treasury, and other public buildings.

**A Cincinnati Knight.**—Dr. A. Ravogli has been knighted with the title of Cavaliere by King Humbert of Italy. The good doctor is to be congratulated, while King Humbert may rest assured the title is most worthily bestowed. Dr. Ravogli has long been the Italian consul in Cincinnati.—*The Lancet-Clinic.*

**Dr. Thomas S. K. Morton** has been elected professor of the principles and practice of surgery in the Woman's Medical College of Pennsylvania, in succession to Dr. John B. Roberts, resigned.

**Dental Practice in Porto Rico.**—At the recent meeting of the New Jersey Dental Association complaint was made that the regulations regarding the practice of dentistry in Porto Rico affect unjustly a number of old practitioners in the island who have been debarred from the further exercise of their profession because they do not hold a diploma from some recognized American college of dentistry.

**The American Association of Obstetricians and Gynæcologists** will hold its twelfth annual meeting in the assembly room of the Denison House, Indianapolis, Ind., Tuesday, Wednesday, and Thursday, September 19, 20, and 21, 1899. The president of the association is Dr. Edward J. Ill, of Newark, N. J., the secretary Dr. William Warren Potter, of Buffalo, N. Y.

**International Congress for the Prophylaxis of Syphilis.**—Dr. Dubois-Havenith, the secretary-general of the congress to be held next month at Brussels, has undertaken the task of preparing a complete bibliography of works, monographs, and journal articles which bear upon the subjects to be discussed, viz.: prophylaxis in syphilis and venereal diseases. The titles of such works by American authors are requested to be sent to the secretary at No. 19 Rue du Gouvernement-Provisoire, Brussels.

**The Colorado State Medical Society.**—The following officers were elected at the annual meeting of this society, held in Denver, June 20, 1899: *President*, Dr. J. N. Hall, Denver; *Vice-Presidents*, Drs. P. J. McHugh, Fort Collins, L. O. Moffett, Colorado Springs, and Millard Harrison, Boulder; *Corresponding Secretary*, Dr. H. B. Whitney, Denver; *Treasurer*, Dr. W. J. Rothwell, Denver; *Recording Secretary*, Dr. Minnie C. T. Love, Denver; *Assistant Recording Secretary*, Dr. W. T. Little, Cañon City.

**Operating Under Difficulties.**—While several physicians of Baltimore were performing an operation on a child not long ago, an explosion of gasoline in the

next room set fire to the house. The fire department turned out and put out the fire, the physicians meanwhile continuing the operation until the heat forced them to remove the patient to another room.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending July 29, 1899. July 24th.—Surgeon L. W. Atlee detached from the *Bennington* and ordered home via *Solace;* Passed Assistant Surgeon G. Rothganger detached from the *Marietta* and ordered home and to wait orders; Passed Assistant Surgeon M. K. Johnson detached from the naval hospital, New York, and ordered to the *Marietta;* Assistant Surgeon W. M. Wheeler, when discharged from further treatment at hospital, Yokohama, Japan, ordered home in the *United States* and to wait orders; Assistant Surgeon T. M. Lippitt detached from the *Solace* and ordered to the *Baltimore;* Assistant Surgeon R. W. Plummer ordered to the naval hospital, New York; Surgeon J. W. Ross, retired, granted leave for one year abroad. July 25th.—Assistant Surgeon H. A. Dunn detached from the *Panther* and ordered to the Washington navy yard. July 28th.—Passed Assistant Surgeon L. L. Von Wedekind detached from the hospital, Cavite, P. I. and ordered to Mare Island, Cal.

**The Zoölogical Distribution of Tuberculosis.**—At the last meeting of the Zoölogical Society of London Dr. Woods Hutchinson, of Buffalo, read a paper on this subject, founded mainly on observations made in the society's gardens. Of two hundred and fifteen necropsies made in the prosector's room during the past six months, forty-nine, or 23.3 per cent. of the mammals and birds, presented the lesions of tuberculosis. This mortality fell most heavily upon the ruminants and gallinæ, and least so upon the carnivores and raptores. Race or family appeared to exert little influence upon susceptibility, mode of housing only a small amount, and food and food habits much more. A close correspondence appeared to exist between immunity and the relative size of the heart in both birds and mammals.

**Deaths from Ptomain Poisoning.**—The conductor of a party of tourists from Philadelphia died a few days ago at a London hotel from supposed ptomain poisoning. Several other guests in the same hotel had been very ill and one has died, supposedly from the same cause.

**Mortality in the Army at Manila.**—According to the Seattle *Times*, the total number of deaths among the United States troops in the Philippines up to June 2d was 722, 23 officers and 699 privates. Of the 23 officers who died, 16 died of wounds received in battle, 2 were drowned, and 5 died of disease. Of the 699 privates, 294 were killed in battle or died of wounds there received, 9 were killed accidentally, 23 were drowned, and 7 committed suicide. One hundred and six died of typhoid fever, 89 of smallpox, 47 of dysentery, 28 of pneumonia, 19 of malarial fever, and 14 of meningitis. Fourteen civilians died, three of wounds received while on the firing line, and the remainder of disease. Smallpox caused some of these deaths.

**Obituary Notes.**—Dr. Robert Hunter, of this city, died suddenly at his summer home in Canada on July 30th. He was born in Scotland about seventy-five years ago, and was graduated in medicine from the New York University Medical College in 1846. He conducted for a time a sanatorium at Plainfield, N. J.—John V. Hamilton, acting assistant surgeon in the United States army, died at Matanzas, Cuba, on July 26th, of chronic nephritis. Dr. Hamilton was appointed from Mississippi and had been in the service for about a year. He was a graduate of the Memphis Hospital Medical College in the class of 1893.—Dr. Louis Alphonse Charpentier, of Paris, a member of the Académie de Médecine, and well known as an authority on obstetrical subjects, died recently at the age of sixty-three years. He took his medical degree in 1863 and was appointed a professor at the Faculté in 1872. He was the author of a "Traité Pratique des Accouchements," and for some years was editor of the *Annales d'Obstétrique et de Gynécologie.*—Dr. Francis Greene died at his home in East Hampton, Mass., on August 3d, of heart trouble, after an illness of several weeks' duration. He was born in New Haven in 1827, and was graduated from the Yale Medical School in 1851. During the Civil War he served on the medical staff in the Peninsular campaign. He leaves a widow.

---

## Obituary.

### DANIEL GARRISON BRINTON, M.D.

PHILADELPHIA, PA.

Dr. Daniel G. Brinton, the distinguished ethnologist, died at Atlantic City, N. J., on July 31st, at the age of sixty-two years. He was born at West Chester, Pa., and was graduated in arts from Yale College in 1858, and in medicine from Jefferson Medical College in 1861. After a year passed in study in Europe he entered the United States volunteer army, and served in the medical corps during the Civil War, becoming medical director of the Eleventh Corps. When disabled from active service by sunstroke, received after the battle of Gettysburg, he became superintendent of hospitals at Quincy and Springfield, Ill., until 1865, when he was discharged with the brevet-rank of lieutenant-colonel. Dr. Brinton was professor of ethnology and archæology in the Philadelphia Academy of Natural Sciences and professor of American archeology and linguistics in the University of Pennsylvania. He was also president of the Numismatic and Antiquarian Society of Philadelphia, and vice-president in 1886 of the American Association for the Advancement of Science, presiding over the section on anthropology. He was for a time editor of the *Medical and Surgical Reporter*, of Philadelphia, and of the *Quarterly Compendium of Medical Science.* Dr. Brinton was a most voluminous writer on ethnological, archæological, and linguistic subjects. He recently presented to the University of Pennsylvania his collection of about twenty-two hundred volumes and manuscripts relating to the aboriginal languages of North and South America.

# Reviews and Notices.

TRANSACTIONS OF THE AMERICAN ORTHOPEDIC ASSOCIATION. Twelfth Session, held at Boston, Mass., May 17, 18, and 19, 1898. Volume XI. Philadelphia: Published by the Association.

THIS volume contains many noteworthy papers, some of which are of exceptional interest. The president in his inaugural address gives an able résumé of the rise and progress of orthopædic surgery in America, and rightly claims that the ten volumes of the Transactions of the Association constitute American orthopædic literature. The book is excellently printed and illustrated, and will prove a valuable addition to the library of an up-to-date surgeon.

BAD NAUHEIM: Its Springs and Their Uses, with Useful Local Information and a Guide to the Environs. By J. GROEDEL, M.D., Medicinalrat, Physician in Bad Nauheim. Second edition. Friedberg and Bad Nauheim: Carl Bindernagel. 1899.

THIS is an enlarged and improved edition of the translation from the German Guide to Bad Nauheim by O. Weiss and J. Groedel. The advances made in treatment at this resort, now so much in the medical public's mind, have been noted, and the chapter on heart disease (which has been made such a feature of the bath treatment) has been considerably lengthened. To physicians intending to send patients for this cure, and to the patients themselves, this work will prove of aid, and will give useful hints to those wishing to carry out similar treatment at home.

LES RAYONS DE ROENTGEN ET LE DIAGNOSTIC DE LA TUBERCULOSE. Par A. BÉCLÈRE, Médecin de l'hôpital Saint-Antoine. Avec 9 figures dans le texte. Paris: J. B. Baillière et Fils. 1899.

THIS little treatise, which was first presented to the Tuberculosis Congress held in Paris last year, embodies the results of the most recent work on the utility of the Roentgen rays in the diagnosis and prognosis of pulmonary tuberculosis. It is interesting to note in the historical introduction that it was Bouchard who, in December, 1897, first demonstrated the presence of an apical infiltration by means of the new rays. The establishment of the diagnosis depends on three factors: (1) The greater opacity of the affected portion, (2) the diminished outline of the diseased lung; (3) the restricted mobility of the diaphragm on the side involved. While the principal value of the procedure is to be found in arriving at an early diagnosis, which is possible in this way long before the usual physical signs put in their appearance, it is also useful in corroborating a diagnosis reached by other means, in revealing the exact extent of lung involved, and in settling the difficult question as to the participation of both apices in the disease. Full details as to the methods of procedure for purposes of differential diagnosis are given and elucidated by adequate illustration.

TRANSACTIONS OF THE AMERICAN DERMATOLOGICAL ASSOCIATION, at its Twenty-Second Annual Meeting, held in Princeton, N. J., May 31 and June 1 and in New York City, June 2, 1898. John T. Bowen, M.D., Secretary.

THIS volume, embracing one hundred and sixty-six pages, is so carefully prepared and systematically arranged that one finds in it a source of great instruction upon the subject of dermatology. Not alone do the Transactions contain such interesting articles as "Hydroa Vacciniforme," by White; "Premycosic Stage of Mycosis Fungoides," by Hyde and Montgomery; "Lupus Erythematosus," by Robinson and White, "Impressions and Conclusions from a Study of Five Thousand Cases," by Allen; "Urticaria Pigmentosa," by Stelwagon, and "Universal Lichen Planus," by Fordyce—but the discussion by the various members is given in full, thus enhancing their value. In addition to the articles enumerated, the report contains some excellent photographs and pathological specimens by Gilchrist, Shepherd, Stelwagon, Johnson, and Fordyce. A special feature of the meeting was the clinical session held at the New York Academy of Medicine on June 2d, where a large collection of photographs, drawings, and microscopical specimens was shown, and a series of rare and interesting cases, as tabulated in this report, was presented. These Transactions differ somewhat from what we are accustomed to see, in that they do not bore one with statistics, membership lists, and other extraneous subjects, but rather form agreeable, interesting, and instructive reading-matter.

PROCEEDINGS OF THE AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION, AT THE FORTY-FIFTH ANNUAL MEETING, held in St. Louis, May 10–13, 1898. Published by the Association.

THIS report of over four hundred pages contains a number of interesting addresses and papers bearing upon insanity and kindred subjects. Dr. Burr, of Flint, Mich., who is secretary, deserves credit for the excellence of the report.

THE READY REFERENCE HANDBOOK OF DISEASES OF THE SKIN. By GEORGE THOMAS JACKSON, M.D. (Col.), Professor of Dermatology in the Woman's Medical College, and in the Medical Department of the University of Vermont, etc. Third edition, revised and enlarged. New York and Philadelphia: Lea Brothers & Co. 1899.

THIS deservedly popular work, to which we have twice before directed attention, has been improved in the revision in various ways. There are now seventy-five illustrations, six hundred and forty-seven pages, and a collection of formulæ in an appendix. The alphabetic arrangement of the subjects without attempt at classification is a feature we especially commended in our original review of the book, and it is this which undoubtedly has helped to make it as popular with students as it has proven to be.

DIE FRUCHTABTREIBUNG DURCH GIFTE UND ANDERE MITTEL. EIN HANDBUCH FÜR AERZTE UND JURISTEN. Von PROF. DR. L. LEWIN und DR. M. BRENNING. Berlin: August Hirschwald. 1899.

THIS work of nearly three hundred pages is intended to set forth the effect of various medicaments, poisons, mechanical and chemical agents upon the process of gestation, with a view to the production of abortion. The first chapters deal with the historical aspect of the subject, tracing abortion from the time of Plato and Aristotle until the present day, with general rules as to the medico-legal side of abortion, its effect upon the mother, the indications for its performance, and the laws of the various lands and races—Jewish, Roman, Greek, French, German, American, etc.—as to its limitations. The next chapters treat of the dynamics of abortion, the special causes of fœtal death with the subsequent expulsion of the uterine contents, and diagnostic elements in criminal abortion. Then follows a very interesting chapter upon the abortifacients used in the various parts of the world; from an historical and ethnographical standpoint this chapter is certainly instructive. The final Chapters VIII. and IX. are of most importance from a medical standpoint, since they deal in a most thorough manner with the various drugs, diseases, and chemico-mechanical agents concerned in the production of abortion. This work from a medico-legal, historical, and instructive standpoint is fascinating beyond a question. We cannot, however, consider it of great practical importance to the general practitioner.

THE STUDY OF THE HAND FOR INDICATIONS OF LOCAL AND GENERAL DISEASE. By EDWARD BLAKE, M.D., Member of the Royal College of Surgeons, Life Associate Sanitary Institute of Great Britain; Member French Hygienic Society; Honorary Member Michigan Medical Society, etc.; Author of "Interchangeable Character of Arthropathies," etc. Second edition. London: Henry J. Glaisher. New York: G. P. Putnam's Sons. 1899.

ALTHOUGH but the short space of four months has elapsed since this work appeared, the author has practically rewritten the material of its hundred pages, making a number of additions. Periodical literature and previous writers are largely quoted. Naturally, in this limited space, exclusive of bibliography, notes, etc., the subject cannot be exhaustively treated. Indeed at times the text seems much too brief for the importance of the subject, and in places even superficial. Some of the illustrations are excellent, while others might be improved upon. Journal articles have often contained more striking illustrations of arthritic states. While a book of this size could be written upon the nails

alone, the reader will find many useful hints as to the diagnostic significance of usual and unusual conditions of the hand.

AN EPITOME OF THE HISTORY OF MEDICINE. By ROSWELL PARK, A.M., M.D., Professor of Surgery in the Medical Department of the University of Buffalo, etc. Based upon a course of lectures delivered in the University of Buffalo. Second edition. Illustrated with portraits and other engravings. Philadelphia: The F. A. Davis Co. 1899.

THAT a second edition of this work should be necessary thus early, shows a much wider interest in matters not strictly practical and of every-day utility than American physicians have often been credited with possessing. The book is one, however, from which much valuable information may be derived aside from its fascinating features both of text and illustration. A chapter on "Iatrotheurgic Symbolism" has been added, having been originally prepared as an oration delivered before the Maine Medical Association in 1898. As the title indicates, the author has presented merely an epitome of the history of medicine and not an exhaustive treatise. There are three hundred and seventy octavo pages, and the book will worthily fill a space in any library.

MAISCH'S MATERIA MEDICA. A Manual of Organic Materia Medica, being a Guide to Materia Medica of the Vegetable and Animal Kingdoms. For the use of Students, Druggists, Pharmacists, and Physicians. By JOHN M. MAISCH, Phar.D., Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy. New seventh edition, thoroughly revised by H. C. C. MAISCH, Ph.G., Ph.D., Professor of Materia Medica and Botany in the Medico-Chirurgical College of Philadelphia, Department of Pharmacy. In one 12mo volume of 512 pages, with 285 engravings. Philadelphia and New York: Lea Brothers & Co. 1899.

THIS justly popular manual continues to offer to the student, pharmacist, and physician a revised repository of accurate data concerning organic materia medica. One feature of the work worthy of note, and having a bearing upon the book's circulation in all English-speaking countries, is the full recognition given to the British Pharmacopœia, and differences in nomenclature have been properly provided for. The convenient size of the book has been maintained despite important and numerous additions.

TREAT'S INTERNATIONAL MEDICAL ANNUAL. Seventeenth year. Cloth, 760 pages. New York: E. B. Treat & Co. 1899.

THIS year book comes as an annual treat covering the advances in the several departments of medical sciences and containing the usual number of original contributions. There is a vast amount crowded into the seven hundred and fifty-eight pages, and for this reason the print is small. Herein lies the chief objection to the work; fortunately for the overstrained eyesight of the physician seeking for knowledge, the text proper is not in such fine print as the index. There are many illustrations, including fifteen full-page colored plates and a number of half-tones.

THE TWELVE TISSUE-REMEDIES OF SCHÜSSLER HOMŒOPATHICALLY AND BIO-CHEMICALLY CONSIDERED. By WILLIAM BOERICKE, M.D., Professor of Materia Medica and Therapeutics in the Hahnemann Hospital College of San Francisco; Member of the California State Homœopathic Medical Society, American Institute of Homœopathy, etc.; and WILLIS A. DEWEY, M.D., Professor of Materia Medica in the University of Michigan Homœopathic Medical College; Corresponding Member of the British Homœopathic Medical Society and of La Société Française d'Homœopathie; Member of the American Institute of Homœopathy, etc. Fourth edition, rewritten and enlarged. Philadelphia: Boericke & Tafel. 1899.

THIS work, now well known, comprises the theory, therapeutic application, materia medica, and a complete repertory of these remedies. The present volume, more complete than its predecessors, one may say, exhausts the subject of the so-called twelve tissue-remedies. The authors, who are by experience abundantly qualified to recognize and avail themselves of all advances or knowledge pertaining to their task, have aquitted themselves well, and now present to the school they represent a complete guide so far as these "remedies" are concerned. There is first an introduction, then follow the materia medica, symptoms, common name, chemical data, etc., followed by an alphabetically arranged therapy, and then the repertory arranged upon a pathologico-anatomical basis, the whole making a work of four hundred and twenty-five pages.

SAUNDERS' MEDICAL HAND-ATLASES. Atlas of Diseases of the Skin, including an Epitome of Pathology and Treatment. By Prof. DR. FRANZ MRACEK, of Vienna. Authorized translation from the German, edited by HENRY W. STELWAGON, M.D., Ph.D. With 63 colored plates and 39 full-page half-tone illustrations. Philadelphia: W. B. Saunders. 1899.

THIS attractively illustrated work forms number seven of the series already noted in these columns. As in most works of the kind, some of the illustrations are excellent while others give a very inadequate or even faulty idea of the actual skin lesion as it appears in life. A history of the case facing the picture helps materially in understanding the condition depicted. The work has been well reproduced and published, and the translator is to be congratulated.

A CENTURY OF VACCINATION AND WHAT IT TEACHES. By W. SCOTT TEBB, M.A., M.D. Cantab., D.P.H. Second edition. London: Swan, Sonnenschein & Co., Limited. 1899.

THIS is a work whose words are directed to the father of the family and to the framer of laws as well as to the author's professional brethren. The tendency of the work appears to be in favor of the abolition of compulsory vaccination, and surely much evidence has been collected from a great variety of sources to strengthen the arguments used. American writers as well as English and those of other countries are quoted to carry the points made by the author. It is shown that on the question of undoubted efficacy and freedom from danger doctors themselves disagree; hence it is not to be wondered at that legislators hesitate to enact laws compelling parents to subject their children to a procedure still, in a measure, in doubt. The work contains a vast amount of data, but one feels that it has not been presented in the most elaborated, digested, and condensed manner possible.

# Clinical Department.

## RAT-TAIL ABSORBABLE SUTURES.

BY E. L. JONES, M.D.,

CUMBERLAND, MD.

SOME years ago I read a suggestion or a query as to the availability of the rat's tail for furnishing a fine and strong absorbable suture for light use, as in eye work, etc., but paid no particular attention to the matter. In 1895, while experimenting with rats, I investigated the tail and found it very easy to get an abundance of tendons, six to seven inches long, from each grown rat, and have used them since as occasion arose. They are easily secured in this manner: Cut around through the skin, a few inches from the tip of the tail, and strip it off like a glove from the finger; with the thumb and forefinger nails pinch between the last joint and its neighbor, and pull out a nice little skein of four to six tendons the length of the tail; if desired, each of these can be unravelled into two or more. Each succeeding joint can be treated in like manner, until the tendons become too short for use. This is easy because the tendons are attached only to one joint and the body. With clean hands and a preliminary washing of the tail, the sutures will be aseptic to start with, and can be kept dry or put in alcohol. There seems to be no difficulty about their absorption, and they are well adapted for light work about the face generally; they easily thread into the finest nee-

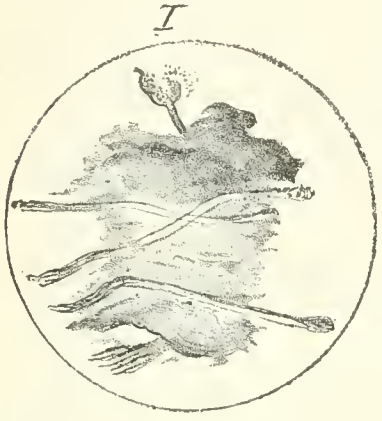
dles. I am not laying claim to originality in this matter, but wish to call renewed attention to a process which does not seem to have attracted as much attention as its usefulness merits.

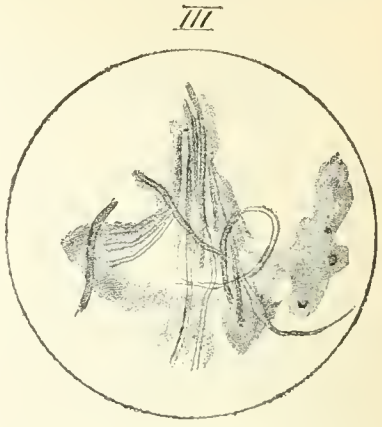
## A MUCOR DERMATOSIS RESEMBLING SCABIES.

By EMIL LUCK, M.D.,

PATERSON, N. J

These three plates have been obtained from a skin affection which has been taken for scabies repeatedly. Looking over the literature, I could find but one case on record in which this zygomycel was pathogenic to man. This case came under the observation of Paltauf: "A laborer died under the appearance of enteritis and circumscribed peritonitis combined with pulmonary symptoms. Post-mortem examination showed ulcers in the intestines, abscesses in the brain, and phlegmons in the larynx and pharynx. Microscopical examination proved it to be a mucor mycosis." These specimens I took from a man fifty-three years of age, silk weaver by trade, of good health. He came to my office saying he was suffering from itch, and nobody could cure it. The affection had the appearance of scabies, the seat of it being also those parts for which the sarcoptes scabiei has a predilection, as the armpits, the skin between the fingers and inner side of the arms, especially near the elbow-joint. He complained about terrible itching, especially at night and when getting warm. He could not sleep all night, and from continual scratching large sore skin abrasions had developed. I examined him carefully, but in hunting after the sarcoptes scabiei failed altogether. There were small elevations which were connected by a duct beneath the horny layer of the skin similar to that produced by the itch insect. On squeezing, a liquid like serum would escape. This was especially the fact in the armpits and at the elbow-joint, which parts were covered all over with small dark red pustules, very much inflamed. Near the margin of this inflamed area I found several solitary spots, some healing, the color being not so intensive. Some of them were covered with a white scab like that of psoriasis. Here I noticed with the aid of a magnifying-glass several filaments emerging from the pustules. I succeeded in extracting several of these, stained them with nitrate of silver, and obtained these plates. They show, according to my knowledge, the characteristic features of mucor corymbifer. No. 1 has been taken from a pustule which was healing but had no scab developed yet. One sporangia is just burst, throwing out the spores. No. 3 was taken from a pustule in the stage of inflammation before development of the sporangiæ. No. 2 was obtained by opening one of the ducts which connected the pustules. I opened it with a needle and extracted the specimen. As Nos. 1 and 3 evidently are mucor corymbifer, I do not know whether No. 2 is the same or mucor rhizopodiformis. I am not sure whether mucor corymbifer sends off filaments as Plate No. 2 shows, but mucor rhizopodiformis does. The affection did not yield to chrysarobin, ichthyol, and red precipitate ointment, but disappeared after application of a three-per-cent. menthol-and-salol ointment.





## A CASE OF TUMOR OF THE BRAIN WITH UNUSUAL SYMPTOMS.[1]

By ARTHUR CONKLIN BRUSH, M.D.,

ASSISTANT NEUROLOGIST TO THE KINGS COUNTY AND BROOKLYN EYE AND EAR HOSPITALS; CONSULTING NEUROLOGIST TO THE BROOKLYN CENTRAL AND BEDFORD DISPENSARIES.

This patient was brought to the clinic at the Brooklyn Eye and Ear Hospital on August 5, 1898. She was a large and well-developed child, eight years of age Her father and mother were both living and healthy. She was the third of four children, the others being in every way normal. She was always a robust child up to July, 1897, when she fell down a flight of cellar steps, striking the back of her head and frightening her very much. Six months later it was noticed that she did not use her right hand, and a few weeks later she lost the use of her right leg. Since that time there have been only very slight voluntary movements on the right side, but vigorous ones occur during sleep. She never speaks and only utters harsh laryngeal sounds. At times she becomes very much excited, laughing or crying without obvious cause. I found upon examination that she was unable to walk, stand, or speak. She seemed fully to understand what was said to her. There was a flaccid hemiplegia on the right side, the only voluntary movements being slight ones of the fingers. All the muscles of the neck were in a state of flaccid paralysis and unable to support the head. All these muscles reacted normally to galvanism, except those of the right anterior group, which did not react to the strongest currents. All the reflexes on the right side were exaggerated. At times she was unable to retain her urine. She was unable to swallow solid food, and the pharyngeal reflex was lost. The pupils reacted both to light and accommodation. Hearing and vision seemed to be normal. On August 19th, while under examination, she began to cry and had a slight general tonic spasm followed by a clonic one. On that day her temperature was

[1] Read before the Brooklyn Pathological Society, November 10, 1898.

100°, her pulse 68 and irregular, and there were bronchial breathing and dulness over the upper half of the left lung. I did not hear of this patient again until the evening of September 30th, when the father came to my office and reported that since I had seen her she had had a number of convulsions and had been for the past twelve hours in a state of constant spasms. He also stated that for some days past she had been unable to swallow even liquids. The child died at six o'clock the next morn.

An autopsy was made eleven hours after death. The dura was everywhere adherent. The brain seemed too large for the skull. It was very light in color and its tissue was extremely soft and œdematous. About the junction of the middle and anterior thirds of the wall of the great longitudinal fissure, in the region which is known as the marginal lobule, both walls were found to be infiltrated by a soft yellowish mass which extended for a distance of about two inches. On the left side the interior of the hemisphere was in the whole frontal and the anterior portion of the parietal lobe occupied by a huge cyst whose wall formed the mass seen in the longitudinal fissure. This wall was composed of a soft, yellow, nodular material, and varied from one inch to half an inch in thickness. The centre of the cyst was occupied by a dull reddish, turbid, semifluid material, the wall of the cyst was quite distinct from the surrounding brain tissue. The corresponding mass on the right side proved to be an egg-sized tumor of the same character as the wall of the cyst. This mass was also easily removed. The pia at the base showed a fibrous meningitis containing gray and yellow tubercles. Examination of the posterior fossa of the skull showed on the right side of the median line, one inch above the lateral sinus, a united fracture with slight displacement running horizontally outward for the distance of three inches. Microscopically the tumor was found to consist of small rounded cells, which were, as a rule, in a state of granular degeneration and without nuclei. Here and there were nucleated cells and small nucleated epithelioid cells. These were embedded in a small amount of delicate reticulated tissue.

It would seem, then, that the etiological factor in this case was the blow which the child received on the back of the head in the fall down the steps. Blows on the head are a well-recognized cause of cerebral tumors, the inflammatory changes thus produced giving rise to cellular changes which result in new growths here just as they do in other parts of the body. It is a well-established fact that every injury to the head sufficient to produce the symptoms of cerebral concussion does so by causing minute lacerations of the brain tissue and small multiple hemorrhages. That the blow was a severe one is shown by the presence of the fracture, while the absence of any history of the symptoms of marked concussion emphasizes the fact that the amount and character of the damage done to the nervous system cannot be measured by the amount of the physical shock. Upon examining the history we are struck at once with the entire absence of many of the ordinary symptoms of tumors of the brain, such as optic neuritis, headache, vertigo, and projectile vomiting. These, however, are not always present, and this is especially true of tumors of the frontal lobes. The paralysis which did exist in this case was certainly not of the organic type. A flaccid hemiplegia which allows slight movements of the extremities, which does not involve the face, which disappears during sleep, in which the reflexes are exaggerated and the electrical reactions are normal, certainly makes a perfect picture of hysterical hemiplegia and the reverse of what we find in the organic type of flaccid hemiplegias. Again, if this hemiplegia was due to the tumor on the left side of the brain, why did not the tumor on the opposite side, which was also of large size and similarly situated, cause motor symptoms? It was the character of the hemiplegia associated with the causeless laughing and crying attacks which led me to consider this case at first to be one of hysteria. It was not until the second visit of the patient that I became convinced that I was dealing with a more serious intracranial difficulty. This mistake is not an unpardonable one, for tumors of the brain, even when of large size, may give only the manifestations of hysteria; and this is especially true of tumors of the frontal lobes, which may give rise to no symptoms beyond psychical ones. It was the character of the convulsion which occurred at the second visit, together with the changes in the pulse, respiration, and temperature, associated with the pulmonary changes, which caused me to change my diagnosis. The acute character of the tuberculosis, and the fact that it was not discovered in several prominent teaching institutions in the borough of Manhattan, leads me to believe that it had not existed for any length of time and was the active factor in causing the death of the child. The real nature of this tumor is a matter of doubt. From its tendency to undergo degenerative changes forming cysts, and from the nature of its cells, one would be apt to consider it a glioma; but gliomas are not distinctly defined like these tumors, but infiltrate the surrounding brain tissue, and are as a rule single. It may of course have been tuberculous, but careful examination failed to show any forms of bacteria. This case, then, only serves to add another to the ones already recorded by Bramwell, Gowers, Starr, and others, of similar cerebral tumors which fail to give the usual symptoms of such growths, but give rise to others which make the diagnosis at times impossible.

11 Lafayette Avenue, Brooklyn, N. Y.

## AN ENORMOUS OVARIAN CYSTOMA.

By D. TOD GILLIAM, M.D.

COLUMBUS, OHIO.

Aside from the enormous size of the growth there were other features connected with the case that entitle it to special consideration. The patient, Sarah Gilham, is a farmer's wife living near Bethesda, Belmont County, Ohio. At the time of operation she was forty-five years of age, and had noticed the growth about thirteen years. She had one son seventeen years of age. She was referred to me by Dr. D. M. Murphy, of Bethesda, who in writing stated that the growth was of sixteen years' standing and intimated that the patient was in bad shape, but said nothing of the extraordinary size of the growth. On arriving in the city she was driven directly to St. Anthony's Hospital, and the doctor came to my office for a permit. I thought little of this at the time, attributing this deviation from the usual custom to the enfeebled condition of the patient. The following morning I was brought into the presence of the patient, and must confess that I was surprised and disconcerted. As she lay in bed on her side with her back to the wall the tumor filled the bed, and as it quivered and vibrated with the respiratory movements it presented a spectacle that I shall never forget. It was simply monstrous, uncanny, and inhuman. In its huge and tremulous expansiveness it reminded one of a mastodonic amniotic sac. A peculiar feature was the comparative laxity of the cyst and abdominal walls, which allowed it to flatten out and spread all over the bed, and it extended from high up on the chest to below the knees. The face, chest, and arms were emaciated to the last degree, while the lower half of the abdomen was knobby and indurated as in elephantiasis. The lower extrem-

ities were truly elephantine in shape and appearance. I could not see the genitalia, nor did I make any attempt toward a vaginal examination, as these parts were obviously inaccessible. She was examined lying on her side, as the pressure of the tumor on the diaphragm gave rise to suffocative symptoms. The percussion wave was strikingly distinct over all parts. She was helpless in bed, and it required the assistance of several persons to change her position. Nevertheless, if placed on her feet she could walk. On the day of her admission, in attempting to change her position in bed the tumor gave a lurch and carried her bodily to the floor. It required the combined efforts of several men and nurses to replace her in bed. She was tall and of large frame, but with the exception of the lower extremities had wasted to a skeleton. She was of buoyant disposition and rather inclined to be jovial. I found her to be a woman of more than ordinary intelligence and shrewdness. She inquired with some show of concern whether the removal of the growth would be attended with danger. On being informed that it would, she expressed a wish to be tapped and sent home. I explained that tapping would be a measure of doubtful expediency, as the refilling of the sac would make such a draft on her vital resources as rapidly to exhaust them, and that the tumor would certainly kill her if it was not removed. She then said that she would leave the matter entirely in my hands. I told her that we would both consider it for twenty-four hours, as I confess that I had little hope of benefiting her.

On my next call we agreed to operate, and she was in the best of spirits. She arrived in the city on Wednesday evening, and the operation was set for Saturday morning. This was March 25, 1899. She took the ether nicely and was placed on the operating table on her side. The bulk of the tumor extended over the side of the table and had to be supported by an assistant. This assistant was relieved at short intervals, as the position was too irksome to be maintained for any length of time. An incision six inches long was made down to the sac and revealed the thickened abdominal walls, consisting entirely of hyperplastic connective tissue. The cyst wall was also thick and dense, and was with difficulty penetrated by the trocar. Thus it will appear that the abdominal and cyst walls had grown *pari passu* with the cystic accumulation, and that neither suffered from the pressure atrophy usually found in such cases. A large wash-tub was placed to receive the contents, which were of the color and consistence of very muddy water. The fluid left a greenish-yellow deposit on anything with which it came in contact. When the tub was nearly full it was removed and a waste-water tub substituted. It required three of these besides the large wash-tub to receive the contents. These tubs were all removed to one side of the room that no extraneous matter might find its way into them. We now placed the patient on her back and attempted to break up the adhesions between the cyst wall and abdominal parietes. These were found to be so dense and extensive that after working a while I became convinced that the method was impracticable, and so opened up the cyst and attempted to deliver by inversion. In this I was also foiled and began to fear that I should have to content myself with an incomplete operation, when suddenly well down on the left side the adhesions began to give, and from this point I was enabled to strip off the sac in all directions. The pedicle was broad and was secured by a chain ligature. The cyst was cut loose and dropped into a receptacle. We now attempted to wash out the cavity, but the two gallons of water poured in disappeared as completely as though poured into a waste-pipe. I now saw that nothing short of a tub of water would avail to flush the cavity, and the attempt was abandoned. The redundant tissues of the abdominal wall hung down on either side of the table and covered the thighs to the knees. The surface was thrown into innumerable folds and fissures, but the folds were much larger and the wrinkling less conspicuous than in other large abdominal growths, because of the unusual thickness of the parietes. In attempting to sponge out the cavity I found pools of fluid in all sorts of out-of-the-way places. At this juncture I found what appeared to be a segment of the cyst wall about the size of a man's hand. It was situated over the bladder and so firmly attached as to preclude any attempt at separation. The margins were clean cut as if severed by the knife or scissors. Neither my assistants nor myself had any recollection of severing aught but the pedicle, and the discovery of this gave rise to no little thought and speculation. After careful sponging and drying the patch was folded on itself longitudinally and the edges were stitched with the Lembert suture. The wound was now closed, but in applying the bandage we found that, do what we would, a large pendulous mass extended down over the thighs. The fluid contents of

the tumor were now measured, a quart measure being used for the purpose. This was done by a sister supervised by the chief nurse. The count was made aloud and repeated by two censors and witnessed by several bystanders. There was no chance for deception or mistake. A quart of the fluid exclusive of the vessel was found to weigh two pounds and a quarter almost precisely. Of this fluid there were seventy-five quarts and a fraction. The cyst wall with its residue weighed a few ounces less than seven pounds. Altogether the tumor weighed a little more than one hundred and seventy-six pounds. The patient did well from the first, although the pulse rate continued at or about 100 for two weeks. The only trouble arose from the maceration and excoriation of the skin in the deep sulci between the contiguous folds, necessitating the use of cotton packing as a protective.

There were present at the operation Dr. J. J. Magruder, chief of staff, who gave the anæsthetic; Drs. E. M. Gilliam and C. F. Gilliam as assistants; Dr. Murphy, the family physician; Drs. W. R. Moore and E. M. Parret as spectators, besides the sister superior and three nurses.

## A SAFE AND SIMPLE METHOD OF REMOVING THE PLACENTA.

By HERMAN GASSER, M D.,
PLATTEVILLE, WIS.

DURING my first two or three years of practice, it was my habit of using Credé's method of expression of the placenta, with general satisfaction to me, but in nearly all cases there was complaint of pain by the patient as a result of the manipulation.

In one rather protracted case of this kind I ordered the patient to press it out while also using Credé's method. It came at once with readiness and ease. It seemed to linger in my mind that at some time or somewhere I had been taught or had read that this might cause inversion, and hence watched with care the contraction of the uterus. Since then in four hundred and eighty confinements it has been my constant practice. At first, it is true, I felt my way gradually, but with ever-increasing confidence, so that at the present time I feel that I can complete the third stage of labor whenever I want to, and that, too, without complaint by the patient and a minimum amount of pain.

After the second stage of labor is complete, it is usually my practice to keep track of things for about ten or fifteen minutes, which also in the mean time gives the patient a rest. I then catch hold of the cord with my right hand, gently grasping the fundus through the abdomen with the left, when I direct the patient to press it out, which she generally does at once. When by gentle traction on the cord and slight compression on the fundus I find it coming, I order the patient to relax her efforts.

Since using this simple and sensible method I have not had any "adherent placentæ" that we hear and read so much about. That they exist, though rarely, no doubt is true. Gentleness and patience should be practised to secure the membranes intact, for much of the future comfort and progress of the patient is dependent upon this seemingly simple procedure.

---

**Chorea.**—Six to ten grains of the oil of gaultheria, either pure or mixed with vaseline, used externally as a dressing for the upper and lower extremities, alternately, evaporation being prevented by the use of oiled silk, is followed by success in many cases. The good effects are not confined to cases with distinctly marked rheumatic symptoms.—LUIGI.

# Society Reports.

## AMERICAN DERMATOLOGICAL ASSOCIATION.

*Twenty-Third Annual Meeting, Held at Philadelphia, May 30, 31, and June 1, 1899.*

**The President's Address.**—DR. JOHN A. FORDYCE, of New York, in his opening address passed in review all the important advances which had been recorded in dermatology since the last meeting, dwelling particularly upon the employment of sera, and the treatment of lupus, hypertrichosis, and other affections by means of the *x*-rays. He did not regard the latter as so efficacious and free from danger of deep burning and scarring in these affections as electrolysis. In speaking of the therapeutic application of concentrated chemical rays (Fennsen) in lupus and alopecia areata, he said lenses of rock crystal had been used to exclude certain rays. As regarded cancer, while the embryonic theory had much in its favor, he believed little doubt existed at the present day as to the infectious nature of the disease. Still the prediction was made that it would be a long time yet before the true pathogenesis became known.

**Epithelioma as a Sequence of Psoriasis and the Probability of Its Arsenical Origin.**—DR. M. B. HARTZELL, of Philadelphia, read a paper on this subject. The case upon which the argument turned concerned a young woman upon whose heel a deep ulceration occurred while she was under treatment by arsenic for psoriasis. As a further evidence that the drug was at the bottom of this intercurrent trouble, there were corn-like thickenings of the palms and the epidermis of the soles became thick and horny. In the left groin was a tumor the size of a small orange, firm and elastic, except at the summit where it was soft. The patient had been given arsenic in considerable doses for a long time, and developed the horny condition of the palms and soles about two years after the psoriasis had made its appearance. Later small superficial ulcers appeared and refused to heal. At this time the tumor in the groin also ulcerated, and discharged abundantly. There soon followed fever, loss of appetite, and rapid emaciation, and death occurred in about two months. Examination of an excised section of the border of the ulcer demonstrated beyond doubt its epitheliomatous nature. Ten cases of associated epithelioma and psoriasis have been reported, the speaker said, and in all of them the psoriasis had been of long standing; in all but three there was some form of keratosis; and in all epitheliomatous change took place beneath one or more of the horny excrescences. In eight out of eleven in which any mention is made of the treatment, arsenic had been given in considerable quantity over a long period. It is noteworthy that in fifty per cent. of the cases the lesions were multiple and that one-half of the patients were under the age of forty years. Dr. Hartzell believed, on the strength of the evidence in our possession, that the epithelioma in these cases was very probably due to the action of arsenic.

In the discussion all agreed that arsenic frequently caused the corn-like elevations described and often marked conditions of keratosis. If the continued irritation of these masses upon the surrounding skin resulted in epitheliomatous changes, then arsenic, it was contended, would have to be looked upon as the remotest cause of the resulting cancer.

**Imperfect or Deficient Urinary Secretion as Observed in Connection with Certain Diseases of the Skin.**—DR. L. D. BULKLEY, of New York, went at considerable length into the analysis of urine as car-

ried out by himself and his assistant over a period of years. The result of the investigations showed that there were no skin affections which were uniformly associated with any particular lack or excess of the normal constituents of urine. In psoriasis, however, the specific gravity was usually high and there was an excess of urea.

In the discussion the opinion prevailed that little could be learned from exhaustive urinalysis, and that while glycosuria was often detected in certain forms of dermatoses, the systematic experiments of Dr. Bulkley would not have to be repeated by others.

Dr. Sherwell said that in pityriasis rosea uric acid was found in excess, and that diuretics assisted in the cure.

Dr. White thought the results of analysis were negative so far as indications for treatment in general were concerned.

Dr. Klotz pointed out the untrustworthiness of Fehling's solution, citing other conditions producing reduction of the copper.

**Two Epidemics of Alopecia Areata in an Asylum.**—Dr. J. T. Bowen, of Boston, read this communication. The chief interest in this report was the fact that it was the first epidemic or epidemics of alopecia to be recorded in this country, though numerous observations of a similar nature have been reported in England, but more especially in France. Sixty-three out of the sixty-nine inmates of an asylum for girls contracted the disease from a girl who entered with bald patches on the scalp. This girl finally left the asylum and was absent three years, in the mean while infecting the lady with whom she lived. Being readmitted to the institution a new epidemic arose, infecting twenty-six out of the then total of forty-five inmates. The areas of baldness were not so typically rounded nor so large as in the cases usually observed, but had a rather angular outline. Still the entire absence of the trichophyton fungus, and the failure to detect any organism which could be accused, led to the opinion that the epidemic was one of alopecia areata.

Dr. J. C. White, having seen some of the cases, gave his opinion that it was not the ordinary form of alopecia as he knew it.

Dr. C. W. Allen stated his belief that there were transition forms between the bald ringworm which resembled alopecia and true alopecia.

**Congenital Dermatitis Herpetiformis and Almost Complete Absence of Finger-Nails and Toe-Nails.**—Dr. S. Sherwell, of Brooklyn, reported a case of this nature. The patient, whose picture was shown, was a woman of twenty-eight years, the offspring of cousins, whose other children were healthy. Some fingers showed rudimentary traces of nails, but with the exception of the great toes the markings of the nail bed were alone visible. This had been the condition since birth, and the dermatitis herpetiformis had existed since earliest infancy; a bulla being discovered a few days after birth. The lesions were confined chiefly to the extremities, especially to the parts below the knee and elbows. There was always much itching. The reader was incined to attribute both conditions to a common neurotic origin.

**A Maculo-Anæsthetic Lepride of the Palm.**—Dr. D. W. Montgomery, of San Francisco, reported this case. The chief point of interest was the unusual location. The patient was a lad aged fourteen years, born in Hawaii, of American mother and Scotch father, and a resident of California for four years. A maternal uncle, aunt, and three cousins were lepers, all having apparently contracted the disease by prolonged association with lepers. When first seen by the speaker the skin over the forefinger was red and swollen, and presented the appearances of a moist eczema. Sensibility was impaired. No bacilli were found. In three months healing had occurred with scar formation. Subsequently there was extension along the palm with analgesia of the area, and the back of the hands showed the condition of non-pitting soft œdemas so often seen in lepers.

**Necrotic Granuloma and Indurated Erythema in the Same Subject.**—Dr. J. C. Johnston, of New York, reported this case. The subject of this observation was a girl aged sixteen years, with tuberculous family history, and enlarged cervical nodes presenting the clinical picture of Bazin's erythème induré des scrofuleux, many of the lesions resembling erythema nodosum before they had become ulcerated. Upon the arms were lesions of an entirely different appearance, but, according to the reader, they were but another expression of the constitutional vice underlying the erythema of the lower extremities. The author's designation, "necrotic granuloma," indicated the nature of these nodules, which have been designated "acnitis and folliclitis," by Barthélemy; "hydradenitis suppurativa," by Pollitzer, "necrotizing chilblain," by Allen; acne necrotica," by Boeck, etc. The lesion was of the chilblain type, of extremely indolent course, and when the central plug separated and slow healing occurred a pit was usually left behind. Treatment was very unsatisfactory. The histological findings showed that the disease began in the lowermost layers of the corium and in the subcutaneous fat. Cell infiltration, etc., began about the vessels and followed their course. The vessels became obliterated, and coagulation necrosis followed. Epithelial changes were secondary. Bazin's erythema and this granuloma were non-microbic, but the latter was thought by the reader to be toxinic. The connection with tuberculosis had been discussed in a recent essay by him on the "Paratuberculoses."

**The Rôle of Pus Organisms in Diseases of the Skin.**—Dr. G. T. Elliot, of New York, opened the discussion on this subject. He reviewed at length all that had appeared upon the subject from the pens of observers and experimenters. He showed that the causes of purulent dermatoses might be of a known chemical or microbic nature, or they might be unknown. Cutaneous infection might occur by metastasis from the interior of the body or directly by the bacteria effecting an entrance through the cutaneous follicles. Saprophytic staphylococci were to be found in large numbers upon the hairy scalp, beneath the nails, and in the perigenital region. Abscesses of the skin and subcutaneous tissue were due to the staphylococcus pyogenes aureus or albus, or to the streptococcus pyogenes. Phlegmon had been shown in ten out of fourteen cases to be caused by the streptococcus pyogenes. Carbuncle was thought by Unna to be due to a special streptococcus, yet experimental inoculation with the ordinary streptococcus had produced the disease. Furuncle was due to the action of staphylococcus aureus. Impetigo vulgaris was claimed by Unna to be produced by an ochre-yellow coccus which he called impetigococcus. He distinguished a number of different forms of impetigo. Folliculitis of lanugo hairs was said by Wickham to be caused by staphylococci. French writers made acne vulgaris dependent upon staphylococci. Ecthyma was thought to be due to the same coccus. Sabouraud claimed that certain tineæ (in the horse) had pus-producing properties. As an instance of metastatic influence the discovery of Neisser's gonococcus in the lesions of furunculosis, occurring in a subject of gonorrhœal urethritis, was cited. Contradictory results were often noted in the bacteriological reports, and the reader found as the result of his investigations that there were other causes for suppurative processes besides the recognized pyogenic micrococci, and that non-pyogenic organisms were capable under favorable conditions of taking on pus-forming qualities. The

whole question was looked upon as being in a still very unsettled condition, and no classification was attempted.

Dr. Gilchrist continued the discussion with a paper entitled "The Bacteriological and Microscopical Examination of Over Three Hundred Vesicular and Pustular Lesions of the Skin, with Some Experimental Observations." The cases which were examined occurred in public and private practice, and were to some extent chosen ones. The following was a summary of his results:

Impetigo contagiosa: Seventeen cases were examined, cultures being taken from the pustules or from beneath the most recent scabs. The streptococcus pyogenes was obtained in pure culture in ten cases and was also present in the other cases, but the staphylococci pyogenes aureus and albus were both present. Smears from the lesions showed the presence of chains of diplococci. The disease was reproduced in a boy, and the pure culture of the same organism was obtained from the lesion.

Ecthyma: Two cases. Pure cultures of the streptococcus pyogenes were obtained from beneath the scabs in both cases.

Impetigo vulgaris, or infected scratch: Sixteen cases. The following organisms were obtained: Streptococcus pyogenes pure in two cases. Five cases yielded the streptococcus pyogenes and staphylococcus epidermidis albus; in seven cases the staphylococcus pyogenes aureus was obtained pure; one case gave the staphylococci pyogenes albus and citreus; one case gave the albus alone.

Tinea sycosis: One case. From a large pustular lesion the tricophyton megalosporon ectothrix was grown pure in one culture, but in the other culture numbers of colonies of the staphylococcus pyogenes aureus were also present. Some of the pure culture of the fungus was inoculated on a man's arm, and a small pustular eczematous lesion was produced. A pure growth of the fungus and no pus organisms were obtained on slant agar from three of the pustules at different times. Smears from the pustules did not demonstrate the presence of any diplococci. The disease was reproduced again on another man's arm with the pure culture obtained from the last case, and again a pure growth of the ectothrix followed a smearing the pus from the pustule over slant agar. Two other cases of tinea megalosporon ectothrix, occurring as discrete pustular lesions over the scalp in negro children, also yielded pure cultures, and no staphylococci or streptococci were present either in the smears or in the culture. One case of tinea megalosporon endothrix was met with on the wrist of a man, and pure cultures of the fungus were obtained from a pustule. The disease was reproduced in two men by inoculation with the pure culture, and the fungus was obtained from the pustules in pure culture.

Furunculosis: Twenty cases were examined. In every case pure cultures of the staphylococcus aureus was obtained.

Scabies: Nine cases. In four patients in whom the lesions were severe and were impetiginous and ecthymatous in character, pure cultures of the streptococcus pyogenes were obtained. In two cases the staphylococcus pyogenes aureus was mixed with the streptococcus pyogenes. In one case only the staphylococcus aureus was obtained from a pustule. In one case a culture from a vesicle yielded the staphylococcus epidermidis albus. In another a vesicle gave the same organism and the staphylococcus pyogenes aureus; and lastly the culture from a pustule in the ninth case was sterile, probably due to faulty technique.

Superficial whitlow: Three cases. One yielded the streptococcus pyogenes and staphylococcus pyogenes aureus; one gave the streptococcus pyogenes and staphylococcus epidermidis albus; one gave the staphylococci pyogenes aureus and albus.

Pediculosis capitis: Cultures from beneath a scab gave the streptococcus pyogenes, the staphylococci pyogenes aureus and albus.

Pediculosis corporis: In one case culture from beneath a scab gave the streptococcus pyogenes and staphylococcus epidermidis albus. In the second case the staphylococcus pyogenes albus resulted.

Sycosis non-parasitica: Three cases. The basal portion of the hair and the pus in each case yielded the staphylococcus pyogenes aureus. In one case of lupoid sycosis culture gave the same micro-organism.

Syphilis: Nine cases. In one case of the small pustular syphilide culture from a pustule gave a pure culture of the streptococcus pyogenes. Two cases of a similar eruption yielded respectively the streptococcus pyogenes and staphylococcus epidermidis albus, and the staphylococci pyogenes aureus and albus. From a case of rupia the pure culture of the staphylococcus pyogenes aureus grew. Cultures from a pemphigoid lesion on the hand of a three-hour-old child were sterile. Pus from a week-old gumma was sterile. The contents of a tubercular lesion were also sterile.

Potassium iodide eruption: Two cases of pustular lesions. One case gave the staphylococcus pyogenes albus; the other was sterile. Cultures from vesicles and pustules produced by the application of carbolic acid, corrosive sublimate, and croton oil respectively gave negative results.

Herpes zoster: Ten cases. Cultures from the vesicles were all sterile, except in one case four small whitish colonies of a short bacillus grew on the media.

Sebaceous cyst: Two cases. Cultures from the contents were sterile.

Dermatitis venenata: Eleven cases. Cultures from the vesicles were all sterile, and even from the pustular lesion no growth was obtained.

Pernio: Four cases. Cultures from the bullæ yielded negative results.

Tuberculosis cutis: In one case the cultures were sterile when taken from the pus. In a second case the streptococcus pyogenes and staphylococcus aureus were present.

Erythema multiforme: Three cases, vesicles and bullæ. The results were sterile. In two cases of herpes iris negative results also followed.

Pemphigus pruriginosus: In one case cultures from numerous vesicles were sterile.

Blastomycetic dermatitis: One case. Cultures from the pus were sterile of the ordinary pus organisms, but a pure culture of blastomycetes was obtained.

Protozoic dermatitis: There was no growth from the pus.

Eczema: Twenty-eight cultures, in nineteen cases. In five cases of eczema vesiculosum, four were sterile; and in one were a few colonies of the staphylococcus epidermidis albus. In thirteen cases of eczema madidans, cultures from the liquid oozing from the lesions in five gave the staphylococcus pyogenes aureus only; two the staphylococcus pyogenes aureus chiefly, and the staphylococcus albus; four gave the staphylococcus epidermidis alone; two were sterile. In ten cases of eczema pustulosum, two gave the staphylococcus pyogenes aureus pure; four gave the staphylococcus epidermidis albus; two gave the staphylococci epidermidis albus and aureus; one was sterile.

Acne vulgaris: Ninety-one cultures from acne pustules of fifty-three patients. Fifty-one cultures were sterile on slant agar; thirty-one cultures gave the staphylococcus epidermidis albus (Welch), and in the large majority of cultures only a few colonies were obtained; nine cultures on glycerin agar gave a pure culture of a bacillus. This bacillus grew slowly *en*

*masse;* it was of a creamy white at first, gradually turning a pinkish red; grew when transplanted *en masse* on blood serum; in glucose agar as a stab without forming gas; invisibly on potato and in bouillon, but not in milk nor in Dunham's solution. It did not decolorize by Gram's method; it was motile and branched (streptothrix). This bacillus was found in all the smears taken from all the pustules, but no diplococci could be found in those which gave sterile results on slant agar.

Since acne vulgaris was by far the commonest of all cutaneous diseases, and its lesions were usually very numerous, it was not impossible to suppose that the pustular lesions of acne vulgaris almost outnumbered all those of all other cutaneous diseases added together. If the fact could be proved, then this bacillus, which is the probable cause of the acne pustules, was the commonest pus producer in all cutaneous diseases. It was somewhat surprising to find that the streptococcus pyogenes outnumbered the staphylococci pyogenes aureus and albus as the next in the series of the pus producers in cutaneous lesions. The staphylococcus pyogenes aureus came next, and the albus next. Another fact which was brought forward was that the majority of vesicular lesions of the skin were sterile, showing that other substances or micro-organisms which could not be grown at present were the cause of these lesions. Other pus producers which were to be added to those just mentioned were tinea megalosporon ectothrix and endothrix, blastomyces protozoa, and tubercle bacilli.

Dr. S. Pollitzer, of New York, made an interesting exhibition of cultures of ringworm and favus, demonstrating the identity of some forms found here with those of cultures he had received from other countries.

**Modes of Infection in Leprosy.**—Dr. P. A. Morrow, of New York, read a paper on this subject. Of late years the view had been gaining ground that contagion could take place or that the entrance of the bacilli could be effected in a variety of ways. There was unquestionably an individual susceptibility and a predisposition to resist which must be reckoned with. Some individuals were practically immune, having a total lack of receptivity. Again, the disease might be inoculable only at certain periods of its existence. Many observers looked upon the skin as offering the most favorable entrance for the bacilli, and in support of this view there was the fact that the lesions first showed themselves upon exposed surfaces. It was here that abrasions, open wounds, bites of insects, mosquitoes, etc., mostly occurred. The mosquito had been credited with playing an important part. It is said that the mosquito and leprosy were introduced into the Hawaiian Islands at the same time, but the reader opposed the opinion that the disease was spread largely by the bite of this insect. The attempt to find the bacilli in the mosquito had until recently always been unsuccessful. Kissing, which is so common in Russia, and rubbing of noses in salutation, as practised in some leprous countries, should prove a fruitful source of infection, especially in view of the frequency of intra-nasal lesions. Catarrhal conditions added to the predisposition. Inhalation must be a common mode of contracting the disease, since the breath of a leper was loaded with bacilli. The reader agreed with the majority of investigators that through the upper air passages most transmission of the disease occurred. Culture plates exposed where lepers were exhaling showed a great abundance of bacilli. Lepers themselves most frequently attributed the onset of their affliction to catching cold, since in leprous countries the disease was apt to be ushered in with symptoms of a "cold."

**The Treatment of Scabies.**—Dr. S. Sherwell, of Brooklyn, read a paper on this subject. He believed that washed sulphur was the cleanest, least disagreeable, and altogether the most efficient remedy at the physician's command, when applied according to the speaker's method. Since the disease usually affected a whole family, it was useless to treat only one member. After a bath, in which the tougher portions might be lightly rubbed with sand soap or sapolio, one-half teaspoonful of the sulphur lotum should be gently rubbed over or into the dry skin, and an equal amount sprinkled between the sheets of the bed or upon the clothing which comes next to the skin. The advantages of this method (which it was not claimed cured in a shorter time than others) were its cleanliness, freedom from production of inflammatory changes, dermatitis, etc., so frequently seen after some other methods, freedom from personal discomfort and from disagreeable odor. It was innocuous and inoffensive, and might be used prophylactically among emigrants, soldiers, etc The reader had employed the method with the greatest success and satisfaction for twenty years.

In the discussion those who were familiar with this manner of using sulphur spoke highly in its favor, while some who had not tried it expressed satisfaction with other methods in common use, and could see no advantage of the dry sulphur over sulphur ointment.

**A Contribution to the Histo-Pathology of Epidermolysis Bullosa.**—Dr. G. T. Elliot, of New York, read a paper with this title. The case described, and which formed the basis of some histological investigations, was one which the reader had on several occasions presented at the meetings of the New York Dermatological Society. It was a typical example of the condition in a man twenty-three years of age, in whom the disease, or, as the speaker preferred to consider and call it, the congenital condition, had existed since birth. The history as to heredity was negative, and there had been no similar instance in the family. The result of the reader's investigations led him to believe that the peculiar tendency in this individual to the formation of bullæ upon the slightest traumatism, friction, or pressure over a given area of skin was due to the fact that he was born with a physiological condition of skin which responded in this way to any slight irritation. As a result of the latter the rete was continually bathed, as it were, in perspiration, was finally swept off, and the bulla then formed.

**Blastomycetic Dermatitis.**—Dr. J. N. Hyde, of Chicago, read a paper on this subject and illustrated it with a series of lantern slides. The reader, who had been assisted in his work by Drs. Hektoen and Bevan, presented the history of a man aged fifty-seven years, with lesions on the back of the hand resembling tuberculosis verrucosa or lupus, together with the histological findings, illustrated by many sections showing the blastomyces, some in the process of budding. This was the seventh case of this rare affection to be recorded in which the causative organism had been cultivated and scientifically studied. The larger number of these were American cases. The reader concluded as follows:

(1) A sufficient number of cases had been recorded, with etiological relations of the disease demonstrated by laboratory experiments, to establish the identity of blastomycetic dermatitis as a dermatosis distinct from all others, and due solely to invasion of the skin by one of the plant forms of the yeast family. (2) This affection was one bearing a close resemblance to certain forms of tuberculous infection of the skin; and while the large number of cases suggesting in clinical aspect the tuberculous nature of the process would, as heretofore, be demonstrated to be such only, yet in a small proportion of such cases it was probable that blastomycetic invasion might have occurred, and such cases required for differentiation exact investigation in

the pathological and bacteriological laboratory. (3) While it was by no means certain that such treatment would benefit every case, the internal administration of the iodide of potassium in every instance of blastomycetic invasion was worthy of trial.

Dr. Fordyce referred to two cases he now had under observation; one in a young girl who had been treated for syphilis and then for lupus. The entire scalp was involved, with loss of hair and superficial white scar formation. The second case involved the bend of the elbow in an ulceration which had existed for fifteen years. The diagnosis of lupus had been made, but the microscope showed no giant cells, while there were the appearances of proliferation and miliary abscess formation such as were present in blastomycetic dermatitis, of which these cases might possibly be unrecognized examples. The interest of these cases in their connection with the cell theory of the cancer controversy was referred to. It was thought that the work done by the dermatologist in helping to solve these difficult problems had not received the attention it deserved.

Dr. Pollitzer pointed out that there were many blastomycetes, while no reason had been advanced why some other form might not produce cancer, as the Italian observers had claimed it did.

Dr. Bowen thought the greatest care should be exercised, in all such cases as that reported by Dr. Hyde, to exclude tuberculosis, which it so closely resembled.

Dr. Hyde said he had examined many cases of tuberculosis and had failed to find blastomycetes.

Dr. T. C. Gilchrist, of Baltimore, reported the death of Dr. Robert B. Morison, of Baltimore, who was president of the association in 1894, and died in September of 1898. Dr. Morison's library, which was rich in dermatological literature, was bequeathed to the Johns Hopkins University.

In the last session of the meeting there was an exhibition of patients, pictures, etc. About two hundred photographs and colored drawings were hung up for inspection. Among the interesting patients shown by Philadelphia physicians were the following: Total alopecia; alopecia areata in negroes; extensive epidermolysis bullosa, for a long time regarded as a pemphigus; extensive *x*-ray burns; lupus treated by the *x*-rays; alopecia areata in brother and sister; dermatitis papillaris capillitii in two negro brothers, with keloid outgrowths; ainhum in a native of New Jersey, with loss of toes and almost complete separation of little fingers.

An exhibition of color photography was made by Mr. Ives, who demonstrated, by means of the "Kromskop," pictures in the natural colors from some of the patients present.

**Election of Officers.**—The officers elected are: Dr. Stelwagon, of Philadelphia, *President;* Dr. Jackson, of New York, *Vice-President;* Dr. F. H. Montgomery, of Chicago, *Secretary and Treasurer.*

---

**Papillitis.**—The many varieties of papillitis which occur independently of intracranial disease indicate that the papilla is a structure prone to be inflamed.—Schweinitz.

The treatment is: First, if possible, to remove the cause. In the beginning of mild cases much can be accomplished by active purgation and the use of diaphoretics. The best treatment, I think, is pilocarpine hypodermically sufficient to produce free diaphoresis. The use of the same remedy locally may amount to something. Blood-letting accomplished nothing as far as I have seen. Alteratives can be used, but they are too slow in their action to effect much.—R. H. Chilton.

## Therapeutic Hints.

**Stomatitis in Smokers.—**

℞ Saloli. . . . . 2
Tinct. catechu . . . . . 4
Spir. menth. pip. . . . . 100
M. S. Teaspoonful in a glass of warm water as a mouth wash.

**Acute Tonsillitis in Children.—**

℞ Tinct. aconiti . . . . . 1
Liq. ammon. citrat. . . . . 30
Syr. aurant. . . . . 20
Aq. destill. . . . . ad 120
M. S. Two teaspoonfuls every three hours.

—Ash.

(From our Special Correspondent.)

ELECTION AT COLLEGE OF SURGEONS—CLOSING SESSION—PRIZES—MALE AND FEMALE PELVES—DECIDUOMA MALIGNUM?—THE "WESTMINSTER REVIEW" AND THE GLOUCESTER EPIDEMIC—RABIES IN IRELAND.

London, July 14, 1899.

The election to the Council of the Royal College of Surgeons went off without any excitement. Only sixteen fellows recorded their votes personally and four hundred and seventy-seven by post. As there are more than twelve hundred fellows this is a poor display of their interest in the college. If the privilege of voting is not worth the trouble of filling up the paper, they might surely be willing to restore it to members. It is possible at least that such a restoration of the usurped right would tend to the prosperity of the college, but the fellows hold to their empty privilege and disdain to use it.

The election resulted in the return of Mr. H. W. Page with two hundred and eighty-six votes, and Mr. T. R. Jessop with two hundred and thirty-three. Dr. Ward Cousins is thus left out, and if he cares much for the honor it seems rather hard on him, for the short time he has served has been subject to the annoyance of re-election. He first entered the council to fill up the remnant of the time of the late Mr. Hulke. Then he had to seek the suffrages of the electors again, and he came in for another remnant of a period caused by the death of Mr. Rivington. That term expires this year, so that Dr. Ward Cousins had to seek re-election for a third time within four years. It is an unprecedented occurrence and suggests reflections on the method of election. Dr. Cousins, as you know, is president-elect of the British Medical Association, and, as the meeting is approaching, he will find work enough in preparing for that to dissipate his chagrin at this election, if indeed he feels any.

The approach of the long vacation is making itself manifest in the schools by the distribution of the prizes. Guy's had a very lively celebration on Friday, Mr. Robert Gordon, the donor of £12,000 to the funds, performing the ceremony. Lord James of Hereford was to have officiated at Charing Cross, but ill health intervened, and his place was taken by Sir Robert Finlay, the solicitor-general. The London Hospital distribution is for next Tuesday, when Lord and Lady Knutsford are to officiate.

Another sign of the season is the closure of wards or hospitals for repairs or alterations. University College Hospital has given notice that the institution will be closed through the month of August. St. George's and King's College hospitals will also be closed for as long or longer. The out-patient department at St. Bartholomew's will be almost shut up. St. Mary's and West London will close their out-patient departments for a couple of months, and there are other institutions where holidays of longer or shorter periods are to be taken. In some of these cases the reason for closing is to enlarge the departments. But is not all this an object-lesson on the abuse of the out-patient system? The general practitioners may cry out that they are being ruined, but hospital managers still enlarge their borders, and the consultants aid and abet them.

The differences in the conformation of the sexes are marked at an early period of development, and no doubt exist earlier than they have been traced. And yet it has quite commonly been taught that the differences in the pelvis do not become manifest until the

age of puberty. If so, it would be an anomaly, for the sexes are clearly enough differentiated in other anatomical respects. Even that most careful Dr. Mathews Duncan seems to have been led somewhat astray by the curious notion that the pelvic differences are established at puberty and suggested in explanation that the bones in the male are thicker and stronger, as well as earlier consolidated. Prof. Arthur Thompson, of Oxford University, has brought this subject before the Obstetrical Society in a paper which is published in full in the *Journal of Anatomy and Physiology*. He assigns to Fehling the credit of discovering that the differences in form and appearance are such as to enable the observer to distinguish the male and female pelvis as early as the third month of fœtal life. Professor Thompson's careful researches corroborate this, and by means of specimens, diagrams, and lantern slides he demonstrated the differences to the satisfaction of his audience.

Dr. Galabin said after this they must give up their ideas as to the difference between the adult and fœtal pelvis, though it might be that at a certain stage of life there might exist what they called infantile pelvis, *i.e.*, one in which the transverse diameters are not so much developed in proportion as in adult women.

Mr. A. Doran (president) said it was quite consistent with biology that sex distinctions of the pelvis should be marked at birth, for it was so with the genito-urinary tract. It would really be far more remarkable if the differences were not established until puberty.

What is deciduoma malignum? The great differences of opinion about this were illustrated at a recent meeting of the Gynæcological Socety, when Drs. F. W. Haultain, of Edinburgh, showed a specimen and gave a lantern demonstration of microphotographs. He considered the condition to be one of chorio-epithelioma.

Dr. Macnaughton Jones was inclined to accept this view, which coincides with that of most continental authorities. The differences met with might be explained as due to typical or atypical forms.

Dr. Eden doubted whether the ninety-one cases which have been recorded would bear careful examination. The new theory had proved fascinating and led to some extravagance, especially in Germany, but there is evidence of a steadier opinion prevailing. Thus the editor of Veit's "Handbuch" has abandoned the chorionic theory and regards the disease as sarcoma modified by pregnancy. So Dr. Haultain admits that the growth presents the broad characteristics of sarcoma. The only peculiar structures in it are the long bands and loops of nucleated protoplasm. The chorionic theory formed so novel a departure from pathological principles that much more evidence is required to sustain it.

Dr. Herbert Snow regarded the disease as sarcomatous, and thought there was no need for a separate nomenclature. He thought, too, that some of the recorded cases were not malignant at all.

Dr. William Duncan deprecated making a special pathology for the uterus. Doing so had only kept gynæcology back many times in the past. Thus he had heard of corroding ulcer of the os uteri, but that was either malignant disease or tuberculosis. He hoped the term deciduoma malignum would soon disappear.

Dr. Haultain in reply said the question was a vexed one, and the difficulty was increased because the cells from which the disease arose were embryonic and not found in adult life. He, too, discarded the term deciduoma malignum as bad, but thought sarcoma worse. He preferred the term chorio-epithelioma.

Readers of the *Westminster Review* must have rubbed their eyes with wonder and doubt when they found in the June number a letter signed A. S. Hunter, professing to reply to Mrs. Garrett-Anderson's letter in *The Times* on vaccination. How such a lucubration could have been admitted to so grave and learned a review threatened to be a literary puzzle. The letter extolled the proceedings of one "John Pickering, F.R.G.S.," who introduced baths containing permanganate as a rapid cure in the smallpox epidemic at Gloucester. Mr. Pickering, said Mr. Hunter, "did not believe so much in infection," although in his pamphlet that person declared his baths would not only arrest the disease, but "kill infection."

This month's *Westminster Review* contains a brief but pungent reply to A. S. Hunter. Perhaps it was for this that the editors inserted his letter and to excite the curiosity of the readers on a tiresome subject. Be that as it may, it is satisfactory to find the journal which was once so closely associated with John Stuart Mill has not fallen into the fallacies exploited by antivacs and other quacks. The reply is from a writer who declares he was in Gloucester during the epidemic (not, like Mr. Hunter, after it) and watched the proceedings day by day. He quotes the report of Dr. Coupland to the Royal Commission to show that the adoption of the Pickering treatment led to the dissemination of the disease, and was to some extent responsible for keeping up the epidemic. Pickering's chief assistant was attacked early and carried the disease to his home, where four of the household were attacked. Ten cases were "directly due to the disinterested labors of those who believed in Mr. Pickering's specific for killing infection." Worse still, people were urged to go out within a few days, and it is impossible to say how many were infected by those who did so. One transgressor of the law was fined by the magistrates for exposing himself while suffering from the disease. Will the public ever give up a ready belief in the statements of every quack or confidence in the assurances of enthusiasts whose chief qualification is ignorance of the points on which they wish to instruct others?

A parliamentary blue-book issued on Wednesday contains a report on the operation of the diseases-of-animals act in Ireland. The veterinary department declares that its experience confirms the opinion of the board of agriculture that muzzling is the only efficient means for exterminating rabies. In 1897 there were four hundred and ninety-seven recorded cases. The order for muzzling came on July 1st of that year. In 1898 the number of cases fell to one hundred and thirty-two. The progress made affords ground for hope "that Ireland will be finally freed from the ravages of rabies." The people who are constantly crying out against muzzling their pets would do well to restrain their selfishness and assist in saving human beings from hydrophobia and dogs from rabies.

## LETTER FROM THE STRAITS SETTLEMENTS.

(From our Special Correspondent.)

PREVALENT DISEASES—SUN FEVER AND MALARIA—SYPHILIS—BERIBERI—LEPROSY—CHOLERA—SMALLPOX—AN OPENING FOR AN OPHTHALMOLOGIST—DYSENTERY.

PENANG, S. S., May 24, 1899.

AMONG the diseases most prevalent in this part of the world, malaria holds the first place. The most common form in which I have met it is the daily intermittent, although I have also seen it in the every-other-day and every-three-days type. There is not much of the type which is ushered in by a distinct "chill," but alternating cold and hot flashes are common. There is a form of fever which is here called "sun fever," which I believe to be malarial in origin. It

begins, so far as my personal experience goes, usually at night time and with a sudden onset of very high temperature, 105° to 107° F. I have met with it only among the Chinese, both immigrants from China and those born here. If the patient does not quickly die from what I take to be shock, he will recover under a good purge and large doses of quinine. I do not think the sun has anything to do with its causation, but would rather class it under the head of pernicious malarial fever, as I think it is just a sudden explosion of accumulated malarial poison, whatever that may be. I have been extremely interested in the reports in your journal regarding the experiments as to the relation of the mosquito to malarial infection. May I just give an instance that has occurred in my own house within the last fortnight? I live upstairs with my family, going downstairs only to meals and when about my work. My servants and five students live downstairs. Mosquitoes are very plentiful both upstairs and down. We all use mosquito curtains, servants and students as well. The last two weeks it has rained a great deal. Every one of the people living downstairs has had malarial fever, and not one of those living upstairs has had it. I was born and brought up in the Wabash Valley, in Indiana, and from the time I can first remember I had what was called there "the shakes." I have been here going on twelve years and have had malarial fever but once in that time, and that was during a furlough home in 1893. When I got back to the old home, I was promptly seized with the same old "fever and ague."

The next most frequent trouble I have met with is some form of syphilis. The ravages made by this loathsome disease are terrible. I thought I had seen it in its worst forms at the clinics and hospitals of Cincinnati, but I was undeceived when I came out here. The native doctors know nothing of its proper treatment, and even if they did the cost of iodide of potassium is so prohibitive that the vast majority of the population, earning as they do but three to four dollars per month, cannot avail themselves of its benefits. The prevalence of syphilis is explained by many on the ground that whereas vast numbers of Chinese men come to these settlements, very few bring their wives. This is compensated for by a regular trade in women and girls brought into the colony for immoral purposes. These women and girls are confined in houses licensed for the purpose, where they carry on, or rather are compelled to carry on, their trade, as it is termed. Being public property, they all soon become diseased and centres of contamination. There is at present no system of medical examination of these women. My own belief is that no system of inspection that included the women alone would prove at all effective in lessening the ravages of this disease. To be effective it should require every inmate of these houses to be free from syphilis, and every man who went in the door should be certified to be free from syphilis also

Beri-beri is a disease confined mostly to the coolie or laboring class, and among them to those who work in opening up new tracts of country, plantations, or tin mines. Almost every medical man has his own theory of the disease, based upon his own experience and methods of treatment. Good food and a prolonged course of tonics seem to effect more good than anything else in the management of this disease. One of the most constant premonitory symptoms of beriberi with which I have met is a constant pain always located at about the lower end of the sternum

Another disease constantly met with is leprosy. There is no proper segregation law in this colony, and so lepers wander around practically at their own sweet will. One meets them everywhere. I have discovered two cases in people in my own employ—one a woman and one a man. In the woman the first thing to attract attention was a constantly occurring sore on the toes of one foot. In the other case the man hurt the big toe of one foot by stepping on a piece of glass, and I found that the toe was anæsthetic. Both these persons were kept under observation for a time, and other unmistakable symptoms of leprosy developed. I tried to persuade them to go to the leper hospital, but they refused, and as I could not compel them to go I had to let them go out to mix with other people at their own pleasure. The government maintains well-equipped hospitals for these people, but residence there is purely voluntary. Horrible sights greet one as he passes through the native portions of the cities and towns, as these people beg piteously for a few cents.

Cholera and smallpox are practically with us all the time, although there has been but one general outbreak of smallpox and none of cholera since I have been here. There are very great opposition and forcible resistance by the natives to segregation and quarantine regulations, and the authorities experienced very great difficulty in controlling an outbreak of smallpox in April of this year.

I think there would be a great field here for an eye-and-ear specialist, as there is a very great deal of eye-and-ear disease. Cataract is especially common. Tuberculosis prevails to a limited extent only. The influenza has prevailed to a large extent on at least three different occasions within the last few years, and appears to have left behind a legacy of weakened constitutions which succumb more readily to the attacks of pulmonary tuberculosis.

As I began my letter with an account of a very prevalent disease, so I will close with the mention of what may almost be regarded as the deadliest foe to human life in these parts, and that is dysentery. It attacks all classes, rich and poor, strong and weak, young and old, and is very fatal. My own experience has been that large doses of ipecac combined with calomel is the best treatment for the acute form, and that a decoction of the bael fruit, or ægle marmelos, is the best that can be done for the chronic or often-recurring type.

---

## LETTER FROM BRAZIL.

(From our Special Correspondent.)

MEDICAL PRACTICE LAW—YELLOW FEVER—TUBERCULOSIS—SYPHILIS—MEDICAL STUDY IN BRAZIL.

São João del Rei, Brazil, June 15 1899

The medical profession of Brazil are very much stirred up just now over two recent decisions in the state courts on the medical law One of the decisions was in the state of Minas and the other in the state and city of Rio de Janeiro. A federal law prohibits the practice of medicine in any of its branches, including dentistry and pharmacy, by any person who has not been approved by one of the two national medical faculties, one in Bahia, the other in Rio, and imposes heavy fines and imprisonment of from three months to a year in prison, upon any one who unlawfully prescribes or administers any medicine or applies any remedy. The two cases above cited were almost identical. A *curandeiro*, an unqualified practitioner, was arrested for the violation of the medical law. His lawyer made the plea that under the constitution of the republic such a law could not be enforced, and the plea was sustained in each case. They justified their action upon the following article of the federal constitution defining individual rights. "The free exercise of any moral, intellectual, or industrial profession is guaranteed." The judges in these cases held that this gives perfect liberty to any one to prac-

tise medicine, while the medical profession maintain that the word "free" in this article of the constitution cannot be forced to mean such great liberty as this. It has not yet been passed upon by the supreme court, but several leading physicians have published long articles in the daily papers showing the absurdity of the judge's decisions.

Juiz de Fóra, about one hundred and fifty miles northwest of Rio, in the state of Minas, is suffering from an epidemic of yellow fever, but it is hard for an outsider to get the facts in the case, as the press and physicians do not care to have the true state of things known, and attribute the deaths to other causes than yellow fever. But, as one of the refugees told me, the cases they call typhoid and malarial result in death as quickly or quicker than the cases called yellow fever. There has been very little cold weather yet this winter, in this state, and the fever continues. Usually we have our coldest weather in June, but so far it has not checked vegetation at all. We rarely ever have frost, but it usually is much colder than this year.

Speaking of yellow fever, Dr. George Butler, an American medical missionary, practising in the state of Pernambuco, has reported a large number of cases treated with small repeated doses of castor oil and turpentine, and says he has not lost a case when the treatment was begun before the action of the kidneys became involved, and when yellow fever was not complicated by some other disease. His treatment is as follows: Three drops of turpentine in a teaspoonful of castor oil every hour for twelve hours, after which only once in two hours until the fever ceases.

The people and profession in Brazil are firm believers in the contagiousness of tuberculosis. A friend of mine, on her way to Rio to embark for New York, passed through the city of São Paulo, and the hotel proprietors refused to give her a room to wait for a train, because she was suffering with this disease. Owners of houses will not willingly rent them to consumptives, and servants will not work for them. They have a great horror of night air, and usually sleep in alcoves without windows, and if at all ailing will not go out in the evening.

Syphilis is perhaps the most common disease in Brazil, as a large portion of cases seen in the hospitals and in private practice come under this head or are modified by it. So common is it that the patients make no effort to conceal the fact of their having it, and they talk about it as freely as they would about a bad cold. It yields readily to treatment, and although it is so common it is rare to see a person disfigured by it as is often the case in the United States, where it is less common.

To secure a diploma it is necessary to take a seven years' course, three of preparatories and four of regular medical studies. The preparatories may be taken in any one of the government colleges, but the medical studies must be taken in one of the two national faculties, and three series of examinations passed—written, oral, and practical. Foreigners bringing a diploma from any reputable medical college are not required to pass the examinations on the preparatories, but are required to take the same examinations as the medical students on all medical studies.

---

**Consumption of Beer.**—It is estimated that the consumption of beer in the entire world amounts to $1,080,000,000 per annum. This seems to be an almost incredible figure, but it does not appear so strange when it is considered that the beer which is consumed throughout the world in a single year would make a lake three and three-quarter miles long, a mile wide, and six feet deep.—*Scientific American.*

## Medical Items.

**A Consumer of Pins.** — Dr. Thomas Annandale reports the case of a twelve-year-old feeble-minded boy who claimed that he had swallowed a large number of pins. He was, however, not believed, because aside from slight epigastric pain he neither complained of nor manifested other noteworthy symptoms. Nevertheless a dose of castor oil was administered, following which he passed per rectum a quantity of straight and bent pins. Within the next fourteen days the following bodies were discharged per vias naturales: fifty-two pins, one needle, five large nails with broad heads, three smaller nails, one shirt-button, four carpenter's nails, and finally three shoe nails. The case is noteworthy, in that the patient was almost free from symptoms, notwithstanding the large number of foreign bodies he disposed of.

**"Superficial Neuralgia" and Its Possible Alliance with Herpes.**—Mr. Jonathan Hutchinson, writing in his *Archives*, says: "A lady who inherits gout and has also in slight form suffered from it, replied in answer to my inquiry as to neuralgia: 'I am liable to superficial neuralgia.' 'What do you mean by that?' I asked. 'I mean that I am liable to have one-half of my scalp become so that I cannot brush my hair without causing pricking pain. It lasts a few days and then goes away completely.' I suspect that many persons are liable to this kind of pain, and that not a few of my middle-aged readers may have experienced it in their own persons. It is a pain very similar, I think, to that which precedes an attack of herpes, but no herpes follows it. I have often thought that it must be allied to herpes and should perhaps be reckoned as one of its abortive forms. It is always strictly one-sided, and its favorite site is the scalp, exempting all other parts of the head and face. It is not attended by much if any sense of pain independently of pressure, but the slightest touch suffices to elicit a crop of tingling pricks followed by a burning sensation. The liability always disappears after a few days, and the recurrences usually have intervals of a few months or it may be years."

**Lord Lister,** says *English Outlook*, was born of Quaker parents in a quiet little Essex town. He was educated medically at the University of London, and soon attracted attention by original work with the microscope. Like many another prophet, however, he had to leave his own country to gain recognition, and at twenty-eight years of age was called to the chair of surgery in the University of Glasgow, and thence to Edinburgh, where in 1870 he published his modest paper upon "A New Method in the Treatment of Wounds," which fairly set the world on fire. There also he married a lady, the daughter of one of Edinburgh's most famous surgeons, whose death only a few years ago left him alone and childless, as solitary in his affections as in his fame. Only after he had won world-wide reputation was he recalled to a chair in his home city, London. A Quaker by birth and for nearly forty years of his life, Lord Lister is the embodiment of the church of his fathers. Sparing of speech, shy of manner, and simple to the verge of asceticism in his tastes and habits, the sweet nobility of his character can be read in his face and seen in his self-forgetful attitude in his work before the world. Never was innocent mortal more embarrassed than when at the great Pasteur celebration a few years ago, the master in his address, after eloquently describing what the world owed to antiseptic surgery, suddenly turned to Lord Lister and, leading him out upon the

platform, embraced him and kissed him upon both cheeks before the widely delighted assembly of scientists.

**Preservatives in Food.**—Dr. Hill, medical officer of health for Birmingham, England, says: "During the three years ending March, 1899, twenty-three hundred of the samples of food received by me as public analyst for the city of Birmingham have been examined for preservatives. In four hundred and sixty instances, or twenty per cent., boric acid, formic aldehyde, or salicylic acid has been detected. This fact will show that the use of preservatives has risen to very large dimensions and requires serious consideration by all interested in the health of the community." What information have we as to the effect of boric acid and borax on health? Several surgical cases have been reported by Moldenkow, Hoguer, Welch, Lemoine, and others, in which the use of these drugs has produced serious and even fatal results. A number of experiments have been made on men and animals by Maltern, Forster, Schlenker, and Chittenden, with the result that they all found smaller or larger doses interfered with digestion and nutrition. *The Lancet* on January 2, 1897, published the opinions of a number of eminent medical men on the subject, who appeared generally to regard the use of preservatives with suspicion, and disapproved of it as likely to produce deleterious effects. *The British Medical Journal* on January 28, 1899, published the experience of Dr. J. Jameson Evans, of Birmingham, who found the continued use of boric acid in cases of cystitis and urethritis produced an erythema followed by a fine scaly exfoliation. Prof. D. J. Leech, of Manchester, has recently expressed the following opinion: "It appears to me that many patients can take either boric acid or borax for a long time in very large doses with impunity, but that in some people the unpleasant results are produced by comparatively small quantities, and it is quite possible that serious harm might in these cases follow its ingestion in the quantities in which it is used in the preservation of food. There can be no doubt that it should not be used to preserve milk."—*Public Health.*

**Seats for Store Assistants in England.**—There has been an agitation in Great Britain recently in favor of providing seats for shop assistants. Indeed, a bill to this effect for Scotland has been introduced to the House of Commons, and possibly would have become law had it not been for a speech of Lord Salisbury, entirely antagonistic to the movement. *The Sanitary Record* comments on the speech of the prime minister of Great Britain in these caustic terms: "Lord Salisbury's speech on the seats for shop assistants—Scotland—bill has occasioned deep disappointment to men of all shades of political opinion all over the country. He pours the vials of his ridicule over the idea of a law which will say when you are to stand up and when sit down, and inquires whether it is proposed to pass a similar law for the benefit of housemaids, and if so, where you are to stop? He objects to the principle of 'grandmotherly' legislation, and believes that more good will be achieved by the growth of humanitarian spirit. Undoubtedly if the humanitarian spirit governed all employers of labor, there would be no need for legislation of this class; the whole of the factory acts might be repealed, and the millennium would be in sight. But it is just because men are not so benevolent as Lord Salisbury professes to believe that laws are required. A large section will always remain hard and selfish and dead to the claims of others; and in the present case the claims of the employees are founded not simply on a desire for greater comfort, but to a right to the consideration of the requirements of health, which is a question of national import and national duty. For girls to be compelled to stand behind a counter as they usually are, for long periods at a stretch, often till late in the evening, is indisputably found to have an injurious effect on their constitutions, and as the remedy is simple, the public is entitled to require that it be provided." Not only in Scotland but everywhere in Great Britain and throughout the whole civilized world, seats should be found for store assistants. When they are not engaged in their duties it seems but humane that they should be permitted to enjoy a little hard-earned rest.

**Increase of Consumption among the Inmates of Prisons.**—Another seeming proof of the contagiousness of tuberculosis has been afforded by the statements made, upheld by statistics, that consumption is greatly on the increase in prisons in the South. Dr. Blake, physician-inspector at the Alabama penitentiary, speaking at the Prison Congress recently held in New Orleans, declared that in Alabama in sixteen years the percentage of convicts to die from consumption had risen from seventeen per cent. to nearly thirty-seven per cent., while during one year—that of 1895–96—above fifty per cent. of the deaths in the penitentiary had been from that disease. Dr. Blake also showed that in the prisons of Mississippi, Texas, Georgia, Virginia, and other States the mortality from tuberculosis has increased steadily. In Texas in 1896 two-thirds of the total number of deaths of convicts were caused by consumption. Dr. Blake is of the opinion that the reason for this high death rate is the fact that tuberculous and non-tuberculous convicts are herded together. This crowding is especially marked in winter, when for the sake of economizing fuel and blankets the convicts are packed into the smallest possible space.

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ending July 29, 1899:

SMALLPOX—UNITED STATES.

### AN ABDOMINO-SACRAL METHOD FOR THE REMOVAL OF RECTAL CARCINOMA.

BY H. OTTO SOMMER, M.D.,

WASHINGTON, D. C.

DURING the time that I have been at Kraske's clinic in Freiburg, I have had the opportunity to observe closely several extirpations of rectal carcinomata performed according to the well-known typical Kraske sacral method, but a recent case was operated upon according to so radical a departure from, or addition to, the original type that it must be considered as a different method and not as one of the many slight modifications to which the original sacral method has been subjected for better or worse. Having the consent of the author, I will herewith make public a description of the operation with a history of the subject upon which it was performed, giving the steps of the operation as they actually occurred, and indulging as occasion offers in such allusions to other procedures as will serve to elucidate the new method and at the same time show the necessity for its existence in the face of the inadequacy of the numerous methods in vogue.

Maria R——, aged forty-nine years; farmer's wife. For the last year the patient has suffered from pains in the abdomen and urging to stool, especially after eating. The pains and inconveniences have grown worse since January. Ten days ago the patient passed a large quantity of blood per rectum in the shape of large black clots. Her family history is good and the history of her early years also, except that seven years ago she began to have "pains in the stomach," from which she suffered for five years.

Present state: The patient is well built but markedly emaciated and cachectic, with a leathery, yellowish appearance of the skin. Her abdomen is distended, a few coils of intestine being distinguishable *de visu*. The presence of a tumor was not determinable by palpation of the abdomen. A slight diastasis of the recti abdominales is noticeable. The colon descendens is filled with movable masses, evidently fæces. Per anum one feels at the height of the sphincter ani tertius a tumor which is firmly adherent posteriorly, as well as anteriorly to the uterus. In this region the intestine is much infiltrated. The tumor is of irregular shape and consists of papilliform projections. Its upper termination cannot be reached. The general condition of the patient was improved by administration of purgatives. The operation was performed as follows:

The tumor was located so high up in the pelvis and was at the same time so intimately adherent to the sacrum as well as to the uterus that every attempt to remove it by the sacral route, however modified, appeared from the first to be impossible, and therefore a combined method, the abdomino-sacral, was applied. Two fingers' breadth above and parallel to the left Poupart's ligament an incision was made dividing the abdominal coverings from the vicinity of the anterior superior spinous process of the ileum to the median line. As the patient was lying with the pelvis highly elevated, the extrusion of the viscera was easily prevented, and the abdominal cavity above could be shut off by the introduction of gauze tampons. In the lowest portion of the sigmoid flexure there immediately became visible a tumor in the wall of the intestine, extending downward into the rectum, and firmly adherent to the uterus and sacrum, but especially to the former; thereupon the peritoneum was transversely incised posteriorly in the region of the promontory, and also laterally and anteriorly in Douglas' cul-de-sac; the mesorectum was also incised. At the same time a large branch of the superior hemorrhoidal was ligated. The peritoneum surrounding the intestine was separated therefrom, and now, working with the fingers alone, the intestine in the region of the rectum was freed from its communications with adjacent parts; this was more easily accomplished posteriorly in the concavity of the sacrum, but anteriorly toward the uterus only with the utmost difficulty, in consequence of which the intestine because of the fragility of its walls was penetrated. After the rectum had been entirely freed from surrounding tissues by means of the hand, which was accomplished with very slight hemorrhage, the great cavity thoroughly packed with gauze, and the patient placed in the right lateral position, the typical sacral incision was made: in the superior angle of the sacral cut one came directly upon the gauze tampons in the cavity which had been created by the separation of the intestine from above downward. Now the carcinoma, which had been entirely loosened from all its surroundings, was easily drawn out through the sacral incision, and after complete walling off of the abdominal cavity by means of gauze tampons the excision of the carcinoma and the anastomosis of the resected gut could be performed with the greatest ease. While Kraske has, up to the case described, practised almost exclusively the sacral operation, of which he is the undisputed parent, with as few variations as possible from the typical method as originally laid down by him, he is inclined to propose this combined or abdomino-sacral method for nearly all cases of rectal carcinomata, and certainly for those in which the tumor is situated high above the anus. This, of course, does not include such growths as are situated externally—or, in other words, confined to the anal region, and which in their treatment do not call for a resectio recti but rather for a far less radical treatment, that is, the amputatio recti. He does this notwithstanding the fact that in one of his earlier communications he says that not only is the high location of a rectal tumor not a contraindication to operation, but nay, more, that a highly situated rectal tumor is more easily removable than a lower; providing, of course, that it is confined to the intestinal wall and easily movable. Further, to show that in advising the new method he does not contradict his optimism in regard to the old sacral method, it is well to remember that in this same earlier advocacy he admits that a highly located tumor may be often very difficult or even impossible of removal if complicated with strong adhesions, although he has occasionally successfully extirpated one; and he adds that in spite of this he considers it more proper to regard a highly situated one as

inoperable when it is complicated by strong adhesions or involvement with the bladder, uterus, sacrum, or promontory, the very obstacles he has successfully combated by the abdomino-sacral method. The advantages to be obtained from the new procedure are obvious, and while at first thought the operation may appear extremely radical and severe, the actual experience gained from the first case decidedly contradicts this apprehension. In the first place the general shock which would first seem natural in consequence of the addition of the first step—the abdominal entrance to the already by no means conservative sacral approach which follows—proved to be no item in the consideration; on the contrary the ease of access to the actual field of operation is so much increased that if anything the general depression is less than would result from an attempt to work through the inadequate posterior entrance alone; and moreover tumors which are practically inaccessible by the sacral route alone become accessible and hence make the abdomino-sacral method almost imperative in certain cases which would otherwise have to be pronounced inoperable. Another great advantage, and one which it is impossible to overlook, is the fact that by this new method the part of the intestinal tract which comes into consideration during the operation is not only rendered more approachable, but can be actually so far drawn out of the sacral wound, and the abdominal cavity so well shut off with gauze tampons, that the removal of the tumor and resection of the rectum can be accomplished, so to say, extraneously to the patient, and with a minimum danger of infection, a danger which Kraske considers of great moment for the prognosis of a good result. Nay more, he considers the possibility of delaying the opening of the bowel until it has been isolated to be almost the chief advantage of the new method, and refers to his former discussion of the sacral method,[1] in which he advises careful tamponade and open-wound treatment after resection, because he considers the danger of peritonitis far less threatening than that of a phlegmon resulting from a penetration of the lumen, and firmly believes that this phlegmon results from an infection derived from the contents of the bowel in this region! Further, the complete removal of the surrounding infected tissues, especially glandular, in which apparently lies the chief source of recurrence of the cancer, after most operations is made possible. Not to be overlooked, however, is the facility afforded by the ligation of important blood-vessels, as described, previously to taking any active steps toward the removal of the growth itself, an advantage which cannot be overestimated in the face of the difficulty usually encountered in this direction, and which frequently necessitates important ligations being performed during the course of evulsion of the growth itself, or at any rate under great disadvantage as to their accessibility.

That the abdomino-sacral method may find almost universal application may be questioned and undoubtedly will be; but that it will be frequently applicable seems clear, for Kraske himself says that in his experience it has been very noticeable that a relatively large percentage of the tumors were situated in the uppermost portion of the rectum, but he frankly admits that it may be mere chance that has brought to his notice such a large percentage. That the possibility of a radical extirpation is a great advantage will hardly be questioned, as it is self-understood that the treatment of rectal carcinoma is the same as for carcinoma elsewhere, namely, a scrupulous removal of all cancerous tissue, including, of course, such glandular tissues as might be the source of the dreaded recurrence; and yet there are at present in France surgeons who oppose all radical treatment and advise the formation of an artificial anus by colotomy. That there are cases in which a palliative colotomy is applicable the most ardent advocate of radical methods will not deny, but they will hardly come into consideration when speaking of curative means. When, however, a colostomy is indicated the practice at this clinic is to make the artificial anus at the transverse colon instead of, as commonly advised, at the sigmoid flexure, not only because it is more easily and rapidly made there than at the immovable ascending and descending portions, but also and especially because in those cases in which it is necessary to follow with the secondary and radical procedure of rectal resection the closure of the artificial anus will be more easily effected. Furthermore it must not be overlooked that a previous iliac colostomy would seriously complicate the latter sacral procedure, owing to the fact that the adhesions formed would either seriously hinder the pulling down of the portion above the resections, or would even absolutely prevent it. The question may be asked, "Since the abdominal preparatory step assists the freeing of the intestine, is not the performance of an iliac colostomy now more than ever in order instead of the transverse incision?" The answer must be that it is actually less necessary than ever, as its presence would prevent the carrying out of the first step; but at the same time this question paves the way to another eminent advantage of the combined abdomino-sacral method, by the very fact that the abdominal incision serves as an exploratory step by which the inoperability or operability of the rectal tumor can be determined, and in the former case a colostomy can be immediately made as a palliative measure, while in the latter the sacral operation can be subsequently performed.

The operation was performed June 9th, and the temperature since operation has varied only between 36.4° and 37.8° C. On the twelfth day the gauze drains were completely removed and renewed. The first few days the patient did not have a free movement of the bowels and consequently suffered from occasional cramps, especially on the 13th, when she had several successive attacks. On the 27th of June, urine first passed spontaneously, and on the same day the patient stood up for a while, and has since done so each day without any ill effects.

In closing I wish to express my thanks to Hofrath Professor Kraske, director of the surgical clinic, for his courtesy to me as an American at a German university, and also to the assistant surgeons, especially Doctor Meisel, to whose division the patient belongs, for their kindly assistance in various directions.

University of Freiburg, Germany, June 29, 1899.

## ACUTE BRONCHITIS—A SYMPTOM; THE TREATMENT FROM AN ETIOLOGICAL STANDPOINT.

By THOMAS F. KEILLY, M.S., M.D.,

NEW YORK.

THIS subject was suggested to my mind by a recent case in which an eminent practitioner of this city was prescribing one of the nauseous mixtures known as stimulating expectorants to a patient having an irritable stomach, and who was then suffering from an attack of acute bronchial catarrh of gouty origin. Further investigation makes it safe to say that a large number of the profession are as blindly using "Stokes' mixture," or some other similar one, to-day in the treatment of acute bronchitis, without any thought of the etiology of the complaint, as did their brethren of a century ago. Certainly this statement holds good as far as the bulk of dispensary practice is concerned.

The term "bronchitis" as applied to catarrhal conditions of the bronchial mucous membrane dates from the writings of Barnham and Falk in the early part of the century. Gradually this symptom came to be regarded as a disease entity. Later views, in the light of clearer pathological findings, lead us to regard it, as well as many other similar affections of the mucous membranes, as only one manifestation of a constitutional disorder.

It has been customary to say that bronchitis is due to "catching cold," and even the latest text-books, almost without exception, mention that as the commonest cause. This term "catching cold" has been handed down for ages as a safe refuge from the too pertinent inquiries of exacting patients. So potent a charm is there in the phrase that beyond its pale no layman may go. Up to fifty years ago it covered inflammatory conditions of every kind from a conjunctivitis to a cystitis. A peritonitis, to the layman, and to many of the profession as well, was due to "catching cold" in the bowels. Even to-day a wound in which one has "caught cold" affords a convenient refuge for many practitioners in cases of cellulitis, infected wounds, etc. It was the cave whence the grim, white spectre consumption issued to begin his ravages. Probably the last den "catching cold" inhabits is the mucous membrane of the air passages. That simple exposure of an otherwise normally constituted individual to a draught of air may cause, by reflex nervous influence, a congestion of certain parts of the air passages cannot be doubted. The experiments of Levy, Bishop, and others have clearly proved this fact. But such a congestion without some morbid agents or agents back of it will not cause a true inflammation, otherwise acute catarrhal affections of these structures would be repeatedly occurring in most individuals. However, should there be a toxic factor present in the blood the congestion will certainly favor the deposition of the toxic material there, thus forming a *locus minoris resistentiæ*.

We know that poisonous matters are constantly excreted by the mucous membranes of the respiratory tract, as well as by the skin and kidneys, and that in the perfect performance of function there must exist a proper balance. If, however, the amount of poisonous substances to be eliminated be greater than usual, and the skin and kidneys cannot excrete it, there will be a deposition of the same at the point of least resistance, and, consequently, irritation of that structure will result. That these poisons should be deposited in the mucous membrane of the respiratory tract sooner than elsewhere is very evident when we consider that here the blood-vessels have less covering, the lymph channels are more superficial, and, in the case of some parts of the mucous membrane of the air tract, the temperature of the blood is lower than in the more deeply placed structures.

Barringer, in speaking of uric acid, suggests that in many cases the poisons are kept in solution while the blood is at a certain temperature, but that whenever, in any part of the circulation, the temperature of the blood falls below that point the solubility of the poisons is diminished, and precipitation is likely to occur. Whether this be true or not is a question; it is a fact, nevertheless, that poisonous matters are deposited in these membranes sooner than elsewhere, and consequently catarrhal conditions occur. Thus, we see the red throat and larynx in scarlet fever twenty-four hours before the other objective symptoms manifest themselves. A preliminary throat irritation almost invariably precedes by several hours an attack of acute rheumatism. In like manner we shall invariably find an irritation of these membranes slightly earlier than the other objective manifestations in all of the acute infections. In many cases when the toxæmia is slight the eruption on the mucous membrane will be the only symptom. In some instances the irritation will be greater in one part of the respiratory passages than in another, but there is generally a slight inflammation throughout the entire air tract.

One of the most brilliant results of such a conception of etiological factors is to be seen in the results of our treatment of many cases of tonsillitis and pharyngitis. A score of years ago it is safe to say that most practitioners were industriously administering teaspoonfuls of tincture of the chloride of iron and chlorate of potash; now all is changed. The antirheumatic remedies go to the root of the trouble in most cases, and the condition lasts half as long.

A similar method of reasoning applied to catarrhal affections of the mucous membrane of the lower air tract would lead to a far more rational basis of treatment than exists to-day. Clinically, it has been customary to recognize as acute bronchitis a condition of increased temperature, a feeling of malaise and sleeplessness, a sense of oppression in the chest, probably due to the determination of a large amount of toxic material to the larger bronchi beneath the sternum, accompanied sooner or later by a bilateral bronchial catarrh. Other signs of a toxæmia are evident in many cases in the impaired gastric functions, headache, myalgia, etc. The fact that the condition is a bilateral one is strong evidence of its constitutional nature. As in every irritation of any mucous membrane, there is a discharge of mucus or muco-pus lasting a week or more, depending on the amount of poison excreted, the toxicity of the same, the individual resistance, and the amount of secondary infection. Naturally the mucous membranes of children are more delicate and susceptible than those of adults, and consequently catarrhal conditions are far more common in them. Probably the commonest cause of this symptom in children is the elimination of toxic products due to decomposition in the gastro-intestinal tract. In dispensary practice the largest percentage of cases in children are due to this cause. In most juvenile institutions attacks of bronchial catarrh are very frequent for a day or so following the regular visiting-days. This is to be explained by the indigestible food given surreptitiously, or otherwise, by friends to the children on these occasions. These attacks, in almost every instance, subside after a purgative and the proper regulation of the diet.

Attacks of this kind are usually characterized by other symptoms of a toxæmia, such as great acceleration of respiration, high temperature, anxious countenance, and marked head symptoms. Faurel has proved that in many of these cases we are dealing with a toxæmia due to infection by the ordinary colon bacillus. It seems very likely that the disturbance in digestion increases the virulence of this organism, that normally inhabits the bowel. Cutaneous manifestations, such as erythema and hives, often accompany such attacks.

The bronchial catarrh accompanying foreign bodies, tubercle, etc., is somewhat different from the symptomatic bronchial catarrh already described. The inflammatory condition, when simple, is entirely local, and is not accompanied by the constitutional symptoms, and it begins less abruptly. The bronchial catarrh of rachitis is essentially a toxic symptom, and is often the earliest objective manifestation of the disease.

After excluding the foregoing there are still, especially in adults, two classes of causes to be considered. The causative factor in by far the larger percentage of such cases, seen in private practice, is the so-called uric or lithic acid poison; that, back of the other, bears an unmistakable relation to the acute infections. When we find people of widely different habits brought into contact for a short time only with a person suffer-

ing from an acute infection, characterized by fever, malaise, and bronchial catarrh, and a short time later we discover that many of these people develop a condition similar to the foregoing, our suspicions are aroused. For this to happen repeatedly, and for the disease to spread by progressive series without feeling that there is an infective agent of some kind causing it, seems hardly possible.

From a review of the literature it seems probable that several organisms are capable of producing affections of this general type. F. Grün claims that he has discovered a germ that was present in all the cases examined, and which was capable of producing a similar condition in others. Dessi has isolated in a similar manner an organism partaking of the characteristics of both the pneumococcus and streptococcus. Claisse obtained a pure culture of a similar organism. By injecting this in the trachea, provided there was an abrasion present, the animal was made to suffer malaise, elevation of temperature, bronchial catarrh, etc., similar to the patient from which the infective material was removed.

Like most other microbic agents, their favorite breeding-places are the haunts of man. It is a common experience that one can often endure severe wetting and exposure in the country, and seldom will any evil result; yet in the same person a slight wetting of the feet in the city will quite often suffice to precipitate an attack of bronchial catarrh by providing a fit soil for the organisms that are lurking there, only waiting for a point of lowered resistance. Nansen and his followers, while in the far Arctic regions, did not contract any catarrhal conditions of the air tract, but as soon as they reached civilization the greater number were thus attacked.

The fault with most of the experimental work in the past is that it has been directed solely to the condition of the air passages, disregarding the fact that inflammation in these structures is but one expression of the constitutional disease.

In cases having a bacterial origin complications are more apt to occur. Relief may be afforded, but they will run a more or less definite course in spite of all our present means of treatment. The possibility that some drug will be found that may act in a way analogous to the antitoxins, or perhaps by destroying the infectious agent itself, as quinine destroys the plasmodia in the bronchial catarrhs of malaria, will always afford an avenue for the hope and enthusiasm of the practitioner.

As before stated, it is the opinion of the writer that the commonest cause of this symptom in adults is the so-called uric or lithic acid poison. This term is intended to embrace the large number of complex substances, more or less closely related to uric acid, that have a similar origin but differ slightly in chemical constitution. Within recent years the relation this poison bears to catarrhal conditions of the mucous membrane has been clearly demonstrated. The relation it bears to many asthmatic conditions has been elucidated by Alexander Haig. Beverley Robinson has called attention to its position in many catarrhs of the appendix. The use of antilithic remedies in many forms of gastric catarrh has been attended with excellent results. The statements contained in L. D. Bulkley's paper, calling the attention of the profession to the great value of sodium bicarbonate in the treatment of catarrhal conditions of the upper air tract, have since been confirmed by many competent observers.

J. Scott Bishop, of Chicago, has proved the relation that this poison bears to coryza and hay fever. His experiments are very interesting, and show that in the morning, when the blood contains most free acid, the lithæmic symptoms are aggravated. That most cases of bronchial catarrh are worse in the morning is a notorious fact. This aggravation is not altogether the result of a collection of mucus due to repose, because it occurs in those who do not sleep at night, and it does not generally occur after sleep at other times of the day.

It is a common clinical observation that bronchial catarrh and rheumatic (lithæmic) affections are (1) prevalent at the same season, and (2) are prevalent under the same conditions. It is during those seasons when there is less fresh air inhaled, less exercise indulged in, more sweets and liquors are taken, that we commonly see these two affections. The skin does not act so freely, and consequently the poisons are stored up awaiting, as it were, a signal to explode. The conditions affording such a spark may be a falling barometer, damp, foggy weather, a sudden chilling of some part of the surface, an attack of indigestion, or some shock to the nervous system. It has long been observed that both affections were common in damp localities and during damp weather.

The hereditary tendency in both lithæmic and bronchial affections is very marked. The frequency of the two classes of complaints in the same individual is also very striking. In many of these patients an attack of bronchial catarrh will alternate with other rheumatoid or gouty symptoms. Often these individuals are aware for several days beforehand of the oncoming attack. Again, the frequency of the two affections is very marked in regular drinkers. To be classed especially among the attacks having a lithæmic origin are the cases recurring periodically. In almost every instance, upon close questioning, a lithæmic history is obtainable from such patients.

Duclos thinks that in these rheumatic cases—(1) the invasion is generally brusk; (2) it involves the greater part of the mucous membrane on both sides very early, and (3) the dyspnœa is out of proportion to the space involved. (4) The râles are dry in those with a gouty tendency and moist in the rheumatic. (5) If not treated, it runs its course unless some other lithæmic manifestation, such as a herpes or an eczema, takes its place. In this connection it may be mentioned that herpes—the "cold sores" of the laity—very commonly occurs in these subjects at the height of the affection and is usually a favorable sign.

In considering acute bronchitis in the light of a toxæmic manifestation we find a ready explanation for the undoubted value of profuse diuresis and diaphoresis in the treatment of this condition. By rapidly eliminating the toxins in this manner many attacks are cut short. In almost every case the patient will experience relief.

From time immemorial expectorants, so-called, have been employed in the treatment of this symptom. That they have some slight effect in relieving the distress can scarcely be denied. By their irritant and congestive action on the stomach they act as local derivatives, much after the fashion of a counter-irritant. That they have any curative effect is problematical. A few are diuretics, and so aid in the elimination of the poison. Any advantages that they may have are more than compensated for by the disturbance of digestion due to their irritating effect, and to the fermenting syrup that affords an excellent medium for the growth of the yeast sarcinæ. Whatever value there is in the ammonia preparations is due—(1) to their antilithic properties, (2) to their local effect on the stomach, and (3) to cardiac stimulation. Other less irritating alkalies will often answer as well.

As far as rational therapeutics can carry us, the indications for treatment point—(1) to the repeated cleansing of the intestinal tract; (2) to aiding the skin and kidneys in the elimination of toxic products by repeated diaphoresis and the ingestion of large

quantities of water; (3) to neutralizing or hastening the elimination of the so-called lithic-acid poison. These poisons, as before stated, are complex and multiple, and in some cases react to one of the antilithic remedies better than to another. Whether the iodides, salicylates, alkalies, or colchicum will be successful in a given case will thus have to be determined. A combination of an alkali with the iodide and salicylate will answer in a large percentage of cases. By means of antiseptic inhalations the danger of secondary infection may often be lessened. It is, however, beyond the limits of the present paper to describe the very many valuable adjuvants to the treatment of the distressing features of this condition.

To summarize: (1) Acute bronchitis is a symptom. (2) The diseased condition of which it is a symptom is a toxæmia, which may be due (*a*) to the so-called uric-acid poison; (*b*) to auto-intoxication from the intestinal canal; (*c*) to specific infectious agents. (3) The treatment with nauseous mixtures, under the name of expectorants, is illogical, and is opposed to modern therapeutics. (4) In every case we should endeavor to discover the etiological factor, and treat the same.

318 West One Hundred and Forty-first Street.

## A CASE OF ASEXUALISM.

By HARLOW BROOKS, M.D.,

PATHOLOGIST TO MONTEFIORE HOME; INSTRUCTOR IN NORMAL HISTOLOGY AT THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; ASSOCIATE IN BACTERIOLOGY AT THE PATHOLOGICAL INSTITUTE OF THE NEW YORK STATE HOSPITALS.

Cases of sexual perversion or of marked anomalies of the sexual organs so rarely come to autopsy, that the writer believes the report of this instance will be of value to those interested in this condition. It seems to the writer that a careful study of a sufficient number of various cases might throw much light on the development of the sexual sense, and on the true relation of the sexual glands to the general system and to the special differential physical and mental development beginning at the time of puberty, which distinguishes the male and female.

The patient was twenty-nine years of age, born in Russia; he was a resident in the United States fifteen years; business, harnessmaker. He entered the Montefiore Home February 8, 1897, and remained there up to the time of his death. He entered with the symptoms of intracerebral hemorrhage, and was treated while resident in the hospital for the resulting paralyses. As this condition has no bearing on the sexual peculiarities of the case, no further mention of it will be made.

At the time of the examination of the patient, it was noted that the voice was high-pitched and the inflection feminine. The physical anomalies to be mentioned later were also remarked at this time. The patient, who remained in the hospital two years, was very retiring and modest in his behavior—"lady-like," as one of the nurses expressed it. During the examination Dr. Frankel at once noticed that he seemingly instinctively attempted to keep the body as much covered as possible, and especially to conceal the genitals.

He denied having ever attempted sexual intercourse of any kind, and stated that he was devoid of sexual desire toward either men or women. He had erections of the penis, but without any particular pleasant sensations and without emissions. While in the hospital, the patient associated but little with the other patients. This may have been partly due to the fact that he was constantly subjected by his fellow-inmates to more or less ridicule, on account of his diminutive sexual organs. As a whole his general behavior, tastes, conversation, and especially his relations toward the other patients were more such as would be expected in a female than in the male, though at no time did he show any sexual manifestations toward the male sex. He died from the results of a mitral stenosis of extreme degree, and at the autopsy the following facts bearing on the sexual condition were observed and are quoted from the protocol:

The body was that of a person of average size, but the lower extremities were of unusual length in proportion to the size of the body; the distance from the anterior superior spine of the left ilium to the arch of the left foot was 1.4 metres. The thighs were massive and the general conformation of the lower extremities was spindle-shaped; there was a slight œdema of the lower extremities from the thighs downward; this was most marked on the right. The musculature was of less volume and less sharply defined than in the ordinary male body of this size. The chest was long and barrel-shaped. The lower border of the ribs extended to within 3.5 cm. of the crests of the ilia. The pelvis was flat and very broad, nearly equalling the breadth of the shoulder girdle. The formation of the upper extremities was also of a somewhat feminine type; the musculature was fairly ample; both forearms and hands were quite œdematous, but the muscles of the right arm were atrophic.

The neck was rather short and unusually full. The head and face were small, and the features were fine, regular, and of a distinctly feminine type. The ears were large and the Darwinian tubercles were especially pronounced. The scalp showed numerous scars due to the tinea favus. The hair of the scalp was fine, dark brown in color, and that in the axillæ, like that over the pubes, was fine, curly, and rather sparse. There was no growth of hair on the face. The body showed a fairly good state of nutrition and the skin was thin and white. There were numerous white spots, which varied from 2 to 10 mm. in diameter over the surface of the body; they appeared like minute scars, but no history or indication of their origin could be obtained; possibly they were trophic lesions resulting from the cerebral hemorrhage.

There was a very large deposit of fat and loose connective tissue over the pubes, giving rise to a condition simulating very closely a well-developed mons veneris, and the growth of hair in this locality was sharply confined to the supra-pubic pad, not extending more or less up the median line as is generally the case in normal males. The penis was small, measuring but 4.5 cm. from its root to the tip of the glans. The organ was well shaped and the glans was fully exposed; a circular cicatrix back of the corona indicated that circumcision had been performed. There were no scars or other evidence of disease or malformation on the glans. The meatus urinarius was very small, barely admitting a 2 mm. probe. The scrotum was represented by a small, transparent, slightly œdematous sac, which apparently contained no testes. The median raphe was intact, well formed, and there was nothing about the genitals to indicate hermaphroditism; the only genital abnormality being the absence of testes, the small size of the penis and scrotum, and the close simulation of a well-developed mons veneris. The breasts were atrophic and the nipples small, presenting no deviation from the usual male type.

Taken as a whole, the body presented a very peculiar appearance, neither male nor female in its general characteristics, but resembling more closely the conformation of the female rather than that of the male.

Examination of the brain revealed the lesion of the left internal capsule which had been diagnosed. The thoracic and abdominal viscera exhibited nothing of interest bearing on the sexual condition of the patient or showing any peculiarities or faults of development;

hence I have omitted these portions of the protocol. Drs. Frankel and Onuf will use the neuro-pathological findings of this case in a study soon to be published by them.

On section it was found that the prominence of the neck was due to hypertrophy, apparently hyperplastic, of the thyroid gland. Of the other ductless glands the thymus was absent. The adrenals were natural and the prehypophysis was slightly enlarged. The larynx was very small, so explaining the high-pitched voice. The pelvis and its contents presented several points of considerable interest. The blades of the ilia were broad, spreading, and shallow, and the bony ring was unusually ample in both superior and inferior straits, so that in its entirety the pelvis presented a quite distinctively female form.

On removing the pelvic peritoneum, a rudimentary testis was found situated subperitoneally on each side. They were bean-shaped and of about equal size, measuring 2.5 cm. in length, 11.5 mm. in breadth, and 3.5 mm. in thickness; both were located at a distance of 4 cm. from the internal ring, with which they were connected by a cord of loose connective tissue and fat which evidently represented the undeveloped gubernaculum. They were surrounded by a considerable quantity of areolar connective tissue, infiltrated with fat. The gross appearance of the cut surface was very similar to that of ordinary testicular tissue. No mediastinum could, however, be seen, and the consistence of the bodies was much more firm than is that of the normal testis. On the posterior surface of the left organ was a small nodular body which was apparently the rudiment of the epididymis, since from it was continued a cord-like structure which passed inward and downward to the posterior surface of the neck of the bladder. This epididymis-like body was not apparent on the right side, where the vas evidently took origin directly in the testis itself. The vasæ were found to be of about the usual size, but on section no lumen could be demonstrated in them. They converged to unite finally each with the duct of the seminal vesicle on the posterior surface of the base of the bladder. The seminal vesicles were much smaller than normal, and attempts at inflation demonstrated them to enclose but a very small lumen, which was obliterated in the greater part of their extent. The ejaculatory ducts were present only as firm fibroid cords, the lumen being obliterated on both sides.

No prostate gland could be made out on gross examination, but a slight thickening was observed in the usual location of this body, and bits of this tissue were subsequently subjected to microscopic examination. The superior surface of the prostatic portion of the urethra was slit open, and the spindle-shaped dilation of this part was found natural and of a commensurate size with that of the penis. The veru montanum was well-formed and proportionately large. On either side of the veru were a few minute perforations which were taken to be the entrance of prostatic ducts. A tiny sinus pocularis was demonstrable just anterior to the veru montanum, but the entrance of ejaculatory ducts was not seen.

Sections across the body of the penis showed its macroscopic appearance to be natural, though the organ was below normal in size.

The internal rings and the inguinal canals were closed on both sides.

The scrotum contained only a small amount of loose connective tissue and considerable œdematous fluid. (Œdema was quite general, as the patient presented extensive kidney and cardiac lesions.)

Microscopic examination of one of the supposed genital glands showed the following structure: The body was surrounded by a fairly thick coat of loosely arranged adult areolar connective tissue. From this capsule passed in dense adult connective-tissue septa which carried numerous blood-vessels. Extending out from these septa was a very intricate network of fine adult fibrils which permeated the section in every direction, even separating the individual cells which are presently to be described. Immediately surrounding the septa were groups of small round cells. These cells were mononuclear and had proportionately small amounts of protoplasm; they were morphologically identical with lymphocytes. Intervening between these areas, which with their enclosed septa made up the bulk of the tissue, were epithelioid cells, which also intermingled more or less in the peripheries of the cell groups just described, and which filled in the remaining spaces of the tissue. These cells were irregularly polyhedral in shape, and varied in size from two to four times that of a lymphocyte. The cytoplasm was granular and in some cells seemed to enclose vacuoles. The nucleus was centrally placed and was frequently irregular in shape. A few of these cells were grouped as though an attempt toward acinus formation was indicated. No evidence of cell activity was seen in any of the elements making up the structure, but, notwithstanding this, blood-vessels were very numerous, though they were mostly poorly formed.

There was nothing in any of the sections which resembled the normal structure of either the male or female genital gland, and under low magnification the appearance was very similar to that of a compound lymph gland.

Sections of the small mass attached to the testis and taken for a rudimentary epididymis show its structure to be similar to that of the body first described, with the exception that the epithelioid cells were much less numous. No evidence of duct formation was present. A few corpora amylacea, mostly situated within connective-tissue whorls, were present.

The slight thickening about the prostatic portion of the urethra microscopically showed a few glandular acini situated in those parts nearest to the urethra. These acini were usually lined by several layers of polygonal cells, but some were completely filled by the cells; in others the most internal cell layer was made up of columnar cells, while those against the basement membrane were still of polygonal form. When a lumen was present within the acini, it was usually partly filled with a homogeneous colloid-like substance or occasionally by a few large, spherical, highly granular cells. The amount of involuntary muscle about these gland-like structures was very small.

It is evident from the above examination that the development of the testes and the prostate gland was arrested at an early stage. The testes have, of course, been entirely functionless, and in all probability the prostate has also been unable to elaborate a secretion, or at least a normal one.

Briefly the chief characteristics presented by the case are these:

1. General habitus and physical development of the female rather than of the male type.

2. Small but naturally formed male external genitals.

3. Undeveloped, non-functionating sexual glands (testes and prostate).

4. Presence of a normal spinal sexual arc, shown by the fact that erections of the penis took place.

5. Absence of all psychic sexual manifestations.

Cases of this nature are clearly defined from the large class of sexual psychopathies in which the sexual abnormalities and manifestations are chiefly or wholly mental. Here no mental sexualism, either normal or abnormal, was present. The case also differs very essentially from those of the various forms of hermaphroditism in which malformations of the genitals, at

least resembling those of both sexes, are present. In our case, all the sexual organs were of a distinctly male type, and aside from their diminutive size were of natural anatomical conformation. Hence I would class this case as a congenital psychic neuter, or as one of psychic asexualism, associated with non-developed sexual glands. It is a well-recognized fact that when castration or ovariotomy is performed before puberty, especially when no mental sexual concepts have been previously formed, the body of the subject develops to a type resembling somewhat that of the opposite sex. Statements that the female subject of ovariotomy becomes "mannish," and that the castrated male becomes "womanish," are, I believe, exaggerated and untrue; preferably we should state that the body assumes a neutral or asexual type. That this form developed from either sex more closely resembles what we choose to call the feminine figure, will, I think, be generally admitted. The cause of this lapse to a neutral physical type after the removal of the sexual glands is in all probability a withdrawal of some internal secretion of these glandular structures.

As confirmatory of this theory are several cases recently reported by Ochsner, who found that when the vas was resected by operation or obliterated by disease the patients still possessed natural sexual desire and power, though, of course, the ability to impregnate was removed, and none of the usual mental or physical changes which ordinarily follow castration developed. Glass also relates a case which strongly supports the internal-secretion theory. A young woman had undergone double oöphorectomy, and as a result sexual desire had disappeared, and the patient complained of numerous neurasthenic symptoms, which are not unusual in these cases. At an operation performed two years after, a normal human ovary was introduced immediately after it had been removed from another patient. A return of sexual desire followed this procedure, together with the disappearance of the various nervous symptoms and the reëstablishment of menstruation.

The mental alterations, while no doubt partly dependent on the same factor, are, I believe, largely subjective; especially is this true of emasculated subjects, such a person being very apt to become an object of ridicule to his more fortunate brethren. This leads the patient to avoid male society, not that he may seek female society, but to escape from the imposed shame and ridicule, preferably to associate with creatures of his own condition or to remain by himself. This is, I think, also the reason that the congenital neuters habitually seek isolation and object to exposure of their bodies.

Congenital neuters, such as the case described in this paper, are not uncommon. Three quite similar cases, all of the male type, are now present in our wards at the Montefiore Home. The condition is, however, I believe much more common among subjects possessing female genitals. Several of these cases have come under my own observation, and gynecologists of experience will be able to recall large numbers. A case of my own was that of a married woman, twenty-nine years of age. The body was not badly formed, though the type was far from a good one of the female figure. The breasts were undeveloped, but the external genitals were of natural configuration. The patient had never menstruated, and expressed herself as utterly unable to comprehend the sexual passion of her husband or that of other women. Internal measurements by means of the sound and bimanual examination showed the uterus to be very small, probably not more than a few centimetres in length. The ovaries could not be felt, and as menstruation had always been absent, I think that we can fairly presume that they were wanting or undeveloped.

A still more striking instance came under the observation of a friend, a general practitioner. In this case the woman was recently married, and consulted the physician because her husband had told her that "something was wrong with her." She had never menstruated, and stated that she had never experienced any sensations of a sexual nature, and the caresses of her husband had never excited anything more than friendly feelings on her part. The figure was of a fairly good form, the breasts were quite well-developed, and the mons veneris, labia majora, and clitoris were all natural. The vagina was represented by only a small pointing inward of the skin.

I do not wish to be misunderstood as inferring that none of these cases has mental sexual manifestations; on the contrary some of them have, and these desires are, just as in the physically natural, sometimes perverted. One of our patients of this class at the Montefiore Home is suspected of having voluntarily amputated his penis, evidently because he thought it neither ornamental nor useful. Similar perversions are seen among eunuchs, and the persistence of not only sexual desire, but of actual gratification, is not unusual in adult females after ovariotomy or complete hysterectomy. I believe, however, that the vast majority are, as the instance reported in this paper, mentally as well as physically essentially neuter, and it seems to me a mistake to class such as cases of hermaphroditism or pseudo-hermaphroditism.

---

## EPIPHORA, OR THE WATERY EYE: ITS COMPLICATIONS, ETIOLOGY, AND MANAGEMENT.[1]

By J. H. WOODWARD, B.S., M.D.,
NEW YORK.

The selection of a subject in ophthalmology for discussion before a society composed for the most part of general practitioners is a task that is not easy of satisfactory accomplishment. When invited to read a paper before you at this time, I decided upon attempting to interest you in a *résumé* of the salient and important factors pertaining to a class of patients who quite as frequently consult the family doctor as the specialist in diseases of the eye. For failure to relieve epiphora is, you know, not very uncommon. I believe this to be unnecessary, and I am forced to the conviction that an important reason why such failure occurs must be sought in the fact that these cases have been too completely surrendered to the care of specialists. It is not possible for the majority of these patients to remain under an oculist's direct supervision very long, nor is it convenient for them to return to him always, should a relapse occur. Under such circumstances, the absence of proper supplementary effort on the part of the patient's physician must inevitably tend to nullify the most skilful treatment, even though it has been applied by the most intelligent ophthalmic surgeon. And it is because of these things that I have ventured to prepare a sketch of this common affection, which, though never a direct menace to life, is always a source of great annoyance to the patient, and is sometimes responsible for the hopeless destruction of an eye.

**Symptoms and Complications.**—Epiphora is a symptom dependent upon a variety of conditions, and characterized by a more or less constant overflow of tears upon the cheeks. The conjunctival space at the inner commissure of the eyelids (locus lacrimalis) is full to running over. This accumulation of liquid frequently blurs the vision of the affected side and so

[1] Read before the New York County Medical Association, May 15, 1899.

disturbs the patient's comfort that he is constantly wiping his eye. The margin of the lower lid and the integument over which the tears flow may become red and may be excoriated, which constant rubbing with a handkerchief intensifies. The conjunctiva of the lower lid and that of the nasal side of the eyeball will become irritable, and sooner or later this irritability may be succeeded by a chronic catarrhal inflammation. The lacrymal sac is not inflamed, nor are its contents abnormal in character or in quantity.

A large number of cases of "watery eye" never exhibit any additional symptoms; and they may be regarded, therefore, as examples of simple epiphora.

On the other hand, there is a considerable number of cases that differ materially from those just described, by virtue of the fact that in addition to the symptoms already enumerated they present others that are dependent upon inflammatory changes in the tear sac. Because of the overweening prominence of the disturbances in the lacrymal sac, the affection is commonly spoken of by ophthalmologists as a dacryocystoblennorrhœa, or as a dacryocystitis. The term dacryocystoblennorrhœa is used to signify a chronic inflammation of the mucous lining of the lacrymal sac, which causes an excessive production of mucus. The term dacryocystitis is used to designate a condition in which the lacrymal sac becomes the seat of an inflammation that causes a purulent or a muco-purulent discharge. Dacryocystitis begins as a chronic process, and may continue indefinitely as such; but the cases are often subject to the occurrence of acute exacerbations. When an acute inflammatory outburst occurs in a lacrymal sac that is the seat of a chronic purulent inflammation, we have to deal with a lacrymal abscess.

In dacryocystoblennorrhœa we have added to the symptoms of simple epiphora the following: (1) Accumulation of a quantity of glairy mucus in the lacrymal sac, the presence of which alone impedes the passage of tears into the nose; and, (2) distention of the sac to form a tumor-like prominence at the inner angle of the eye (mucocele). Evacuation of the sac, in this affection, as well as in dacryocystitis, and diagnosis of the nature of its contents is effected by means of digital pressure over the region of the sac, which forces at least a portion to pass through the canaliculi and puncta into the eye, where it may be examined. In a relatively small number of cases, unless the direction of the pressure be carefully regulated, the contents will all run through the nasal duct into the inferior meatus of the nose, and escape observation. Dacryocystoblennorrhœa may continue a number of years without alteration in the nature of the discharge; or, gradually or suddenly, the inflammatory process may assume the characteristics of a dacryocystitis.

In dacryocystitis we have the symptoms already enumerated for simple epiphora and dacryocystoblennorrhœa, with this modification, that the discharge from the lacrymal sac is purulent or muco-purulent. The presence of pus in the discharge works a marked alteration in the importance of these cases. All the symptoms are apt to be intensified. The eye weeps more profusely; the blepharitis is more marked; the conjunctivitis is more intense; the eyelids are commonly stuck together in the morning; and vision is more disturbed than in the other cases. Should an abrasion of the cornea occur from any cause, the uncovered spot will become infected by the discharge from the lacrymal sac, and a destructive ulceration will ensue immediately. It is even possible that constant exposure of the normal cornea to such infectious material may induce ulceration of its structures. At all events, when the epithelial layer of the cornea is destroyed in cases of dacryocystitis, either by traumatism, or by operative measures, or by pathological processes, a destructive infectious inflammation immediately springs up in the exposed part, and ends in partial or total destruction of visual power in the affected eye, or in loss of the eyeball itself.

It has been noted already that dacryocystitis is a chronic process. Many cases run on for years, presenting only the symptoms of a weeping eye and a more or less profuse purulent or muco-purulent discharge from the lacrymal sac, which either slowly escapes through the puncta into the eye or is expressed in quantity from time to time by the patient. A large number of cases, however, have acute exacerbations (lacrymal abscess). Such attacks are frequently diagnosticated as erysipelas of the face.

Without any warning the tissues about the lacrymal sac become swollen. The tumefaction closes the eye, and may obliterate the natural depression at the inner angle of the orbit. The skin takes on an erysipelatous blush, which may spread over the whole side of the face. General prostration may be marked; and a febrile movement will be observed. The inflammatory process which began in the lacrymal sac has extended to the circumjacent structures, and has terminated in abscess formation outside of the tear sac, but communicating with it. Sooner or later the abscess is incised, or it ruptures spontaneously on the cheek; then the acute symptoms begin to ameliorate. Under antiseptic handling suppuration diminishes rapidly, the inflammatory induration soon passes away, and the external wound closes. Under other circumstances, the suppuration is prolonged, the induration subsides slowly, and a lacrymal fistula is established at the point, or the points, of rupture. The skin may be undermined by numerous fistulous tracts, and its surface broken by superficial ulcerations. Some cases present appearances resembling those of epitheliomatous degeneration at the inner canthus. Scarring of the face and deformity of the lower eyelid may be irremediable sequelæ of a lacrymal abscess.

**Etiology.**—The causes of epiphora may be grouped under two subdivisions: (1) Conditions that induce an excessive production of tears; and (2) conditions that interfere with the proper function of the drainage system.

In the former, the drainage system may or it may not be normal; in the latter, the production of tears may or it may not be normal.

(1) The conditions that induce an excessive flow of tears are: emotional states; acute and chronic inflammations of the conjunctiva; irritation or inflammation of the cornea, iris, choroid, or retina; foreign bodies in the eye; eye-strain from excessive use of the eyes, or from using them in bad lights and during enfeebled states of the general system; and eye-strain due to errors of refraction, or to anomalies of the ocular muscles; cold winds, and irritating vapors and substances in the air; and reflex irritation produced by states of the nasal chambers and by other things that increase the sensibility of the fifth nerve.

(2) The drainage system of the eye is composed, as you know, of the superior and the inferior canaliculi, the orifices of which, known as the puncta lacrimalia, are found at the posterior edge of the eyelid near the inner canthus. The canaliculi empty into the lacrymal sac, which carries the tears to the nasal duct. The latter passes through a bony canal and empties into the inferior meatus of the nose on the outer side of the inferior turbinated bone.

In order that this system may properly perform its function it is essential that its ways be patent, and that the puncta should lie in gentle contact with the conjunctiva of the eyeball, and that the lower extremity of the nasal duct should discharge into an unobstructed inferior meatus. The tears—comprising the secretion of the lacrymal gland, the glands of Krause, and the mucous follicles of the conjunctiva—are moved

toward the inner canthus by force of gravitation, and by the act of winking. They enter the drainage system by virtue of the forces of capillarity and gravitation, and by the same influences they are conducted through the drainage system and discharged into the nose.

The conditions which suspend or impair the function of this system operate in mechanical ways, and naturally group themselves in the following manner:

(1) Conditions pertaining to the puncta lacrimalia.

It has been said already that the puncta must lie in gentle contact with the bulbar conjunctiva. They must be patent and of sufficient calibre to take up the tears. While these things may be predicated of both puncta, it should be noted that the inferior punctum and the inferior canaliculus are very much more important in this connection than are the superior canaliculus and the superior punctum. And, whenever reference is henceforth made to a punctum or a canaliculus, it will be understood, unless otherwise specified, that reference is made to the inferior group; although nearly every statement that I may make regarding the one may be truthfully applied to the other.

The edge of the eyelid may be everted (ectropium) so that the punctum cannot collect the tears, or it may be inverted (entropium), with the same result. There may be congenital absence of the punctum; or it may be constricted or obliterated by cicatrices due to wounds or burns, or pathological ulcerations.

(2) Conditions pertaining to the canaliculi.

Abnormal conditions of the canaliculi may consist in their congenital absence; or they may be constricted or occluded by the same causes that constrict or occlude the puncta. They may be obstructed by foreign bodies—*e.g.*, eyelashes and lacrymal calculi—or by mucous polypi. The punctum may be removed from contact with the eyeball, and the lumen of the canaliculus may be encroached upon by hypertrophy of the caruncle. The calibre of the canaliculus is frequently obstructed by a stricture at the point where it enters the lacrymal sac.

(3) Conditions pertaining to the lacrymal sac.

Chronic inflammation in the lacrymal sac, by virtue of the consequent swelling of its mucous lining and the viscidity of the discharges retained in the sac, seriously impedes the passage of tears through the drainage system. This is, no doubt, the most important complication that we commonly encounter. The reason why such inflammation ever occurs is not easy to determine. If infection of the mucous lining by micro-organisms is the cause of it, whence do they enter the tear sac? Clinical experience demonstrates, I think, that they do not often come from an inflamed conjunctiva. After dacryocystitis has set in, there is no doubt that the discharge is infectious. The conjunctiva is frequently infected by it, but evidence that the mucous membrane of the lacrymal sac is ever infected from the conjunctiva is difficult to find. One would suppose, for example, that gonorrhœal ophthalmia would infect the tear sac with great certainty; but I doubt if there be an ophthalmologist in this city who has ever seen an example of such infection. It seems to me far more probable that the inflammatory process in the tear sac is propagated, in certain instances, from the nose through continuity of tissue; while, in other cases, it is induced primarily by virtue of continued reflex dilatation, both of the veins of the lacrymal sac and of the veins composing the plexus surrounding the nasal duct in its bony canal, caused by irritations of the fifth nerve in its septal and turbinal distributions. Common observation teaches daily that chronic congestion of a mucous membrane is accompanied by an excessive production of thick mucus; and that a purulent infection is readily grafted upon such a condition.

Cicatrices of burns or wounds, or ulcerations, may occlude or deform the lacrymal sac so as to suspend its function as a section of the drainage apparatus.

(4) Conditions pertaining to the nasal duct.

Inflammatory stricture occurs at the upper extremity of the nasal duct, and at its opening in the inferior meatus. It is less common, however, than are strictures at the nasal end of the inferior canaliculus. Chronic dilatation of the plexus of veins about the nasal duct is, I believe, the most common cause of loss of function in this part. Bony obstructions due to fracture have been encountered. But the lumen of the nasal duct is far more commonly encroached upon by bony formations developing from an osteoplastic periostitis in the bony canal, that has been excited by violence in probing the nasal duct, or by excessive probing. Tuberculosis, gummata, and invading tumors have been recorded as obstructions in the nasal duct. False passages made by forcible probing would naturally impair the function of the drainage system.

(5) Conditions pertaining to the nose.

Finally, rhinitis, acute and chronic, hypertrophic and atrophic, plays an important rôle in epiphora. Hyperæsthesia of the fifth nerve should not be forgotten in this connection. Deviations of the septum and septal spurs, when they interfere with the function of the nose, and intra-nasal growths of every sort, have important etiological bearings upon these cases, and ought never to be neglected.

**Treatment.**—I think all will agree, that for a little thing epiphora has a tremendous etiology. It must be evident to every one that the management of it consists in much more than probing the nasal duct. But complete discussion of the treatment of the various causes that induce the symptom would, of course, be out of place now, because unneccessary. Simple enumeration of the etiological factors is sufficient to suggest to every one the proper handling; and I shall conclude my remarks, therefore, with a few observations upon the purely local management of some of the conditions that impair the function of the drainage system.

(1) Punctum and canaliculus.

We have seen that the size and position of the inferior punctum are altered in a certain proportion of the cases. Narrowing of the lumen of the punctum is common, and may be detected best by attempting to introduce the smallest lacrymal probe—00. Eversion of the eyelid may be very slight indeed, and yet be sufficient to remove the punctum from proper contact with the eyeball. For both of these conditions, removal of a V-shaped segment from the posterior wall of the punctum and canaliculus is the most satisfactory procedure. The canaliculus will not collapse when cut into, but maintains its form very much like a rubber tube under every sort of manipulation. Having removed the V-shaped segment the patency of the drainage system may be estimated by injecting a solution of boric acid into the canaliculus by means of a hypodermic syringe provided with a blunt needle, or by passing lacrymal probes. I prefer to syringe all cases first, and avoid probing whenever it is possible to do so.

When the canaliculus is insufficient, and when there is a stricture at its nasal extremity, the custom is to divide longitudinally the posterior wall of the canaliculus, cut the stricture, and pass the largest probe that the nasal duct will hold. It seems to me, however, that simply slitting the canaliculus is not sufficient. The edges of the wound will lie in contact with one another, and hence the freedom of drainage will not be much increased by the operation. For a number of years, I have been in the habit of remov-

ing, instead, a portion of, or the entire length of, the posterior wall of the canaliculus. I am convinced that the results obtained have been much better for this change in management. Frequently, I have noted also that the caruncle was sufficiently enlarged to pass upon the canaliculus. In common with others, I formerly used astringents, hoping to reduce the size of the caruncle thereby. In the milder cases, no doubt, that treatment will succeed. But in the more marked cases, the caruncle should be cut away. During the past six or seven years, I have practised this small operation upon a considerable number of cases, and I am pleased to believe that the results have been satisfactory to me and to my patients.

Incision of the stricture at the extremity of the canaliculus, when made freely through the lower segment, will usually permit the immediate passage of a very large probe—No. 9 Theobald, in adults. During healing of the wound, occasional probing is necessary to obviate reformation of the stricture. After that period has passed, frequent probing will irritate the parts to their detriment. Should obstruction still exist, the opening into the lacrymal sac ought to be enlarged by cutting away its posterior margin with scissors.

The posterior wall of the canaliculus, and the caruncle, should be removed in cases of chronic inflammation in the lacrymal sac, and all strictures should be thoroughly divided. This treatment will change the conditions so that it will be easy for the patient to express discharges from the tear sac. As large probes as possible should be passed through the nasal duct, but always without force sufficient to injure the mucous membrane. Probes should be used in these cases according to the principles upon which sounds are used in the urethra, and it should not be forgotten that repeated probing will often do more harm than good.

Syringing with a saturated solution of boric acid may be practised in chronic inflammation of the tear sac daily, until the discharge has ceased. It is not safe to attempt to syringe through the nasal duct immediately after dividing strictures, nor is it safe to inject into the passages of the drainage system irritating solutions like those of nitrate of silver or chloride of zinc. For, in either instance, orbital cellulitis with its serious consequences may follow the injection. Under all circumstances, the various manipulations with probe and syringe should be gentle. Each physician ought to be able to do these things as skilfully as another, for there is nothing difficult about them. And it is owing to the fact that they are not practised by the family physician that some cases of inflammation in the tear sac resume their former proportions after leaving the ophthalmic surgeon.

When inflammation in the tear sac has been subdued, the syringing may be discontinued. But the patient should occasionally medicate his drainage passages, by lying upon his back with his head low and filling the inner angle of the eye with the boric-acid solution, which, after a few minutes, will run through into the nose.

Relapses are commonly due to attacks of cold in the head. When they become manifest, the probe should be passed, and the syringing resumed, according to circumstances.

Lacrymal abscesses are treated like other abscesses. As soon as the acute symptoms have subsided the chronic condition in the drainage system may be attacked.

Failure to cure inflammation in the lacrymal sac by the means referred to may induce the surgeon in bad cases to consider the advisability of extirpating the lacrymal sac. Before this is done, however, the patient should be put under a general anæsthetic, and the sac should be thoroughly curetted, and packed with iodoform gauze. This may be accomplished without making a wound through the skin. It will be advisable in most cases to irrigate and repack the wound daily. By the end of a fortnight, irrigation only will be sufficient.

Extirpation of the lesser lobe of the lacrymal gland has been especially extolled by de Wecker, for simple epiphora. It will diminish the secretion of tears, and may be advised for cases that prove obstinate. But it must not be forgotten that even extirpation of the entire lacrymal gland will not alone cure simple epiphora.

There are undoubtedly cases of suppurative inflammation in the lacrymal sac that are severe enough to warrant extirpation of the sac. The lacrymal gland should be removed also, for otherwise the epiphora will be almost unendurable. Removal of the gland appears to be, in general, a perfectly safe operation. The glands of Krause and the mucous follicles of the conjunctiva will secrete sufficient liquid to keep the parts properly moistened and lubricated. The cases, however, in which removal of the entire gland is indicated are seldom seen.

Finally, it is needless to add that the strictest asepsis is essential to success in every ophthalmic operation. Cocaine will produce sufficient anæsthesia for nearly all the work in the cases we have been considering. Should cocaine fail, or should the patient be timid and nervous, a general anæsthetic ought to be used.

58 West Fortieth Street.

## THE OPERATION OF CŒLIOTOMY.[1]

By ROBERT BANCKER TALBOT, M.D.,

ASSISTANT SURGEON AT THE WOMAN'S HOSPITAL, STATE OF NEW YORK.

The operation of cœliotomy has changed so greatly during the last fifteen years, that in looking backward over that period of time it is hard to realize that the methods then pursued could be followed with any great degree of success; for the lack of asepsis, in fact the general want of cleanliness, warrant me in making this broad assertion, and as I look still further back it would seem as if the operations of this character were almost rudimentary compared with the operations of to-day.

Gynæcologists worked along in their line doing plastic work, and doing that plastic work more or less successfully, but when it came to a cœliotomy they felt and acted as though they had finally come to an operation which to them seemed to be the climax of surgery in their line. The late Dr. Edward Peaslee once made the remark that ovariotomy was the keystone of gynæcology. In those days, cœliotomy was to the average man an operation to be dreaded, on account of the danger to the patient, and one of serious damage to the reputation of the surgeon in case of failure. And I can remember well when many a good case was turned away from the hospital because the surgeon was unwilling to take the risk. To-day, pause and see where we stand. Every post-graduate matriculate who can handle the scalpel with any amount of dexterity will undertake to do cœliotomy with comparatively little fear, and even the young hospital interne expects to do his two or three cases of cœliotomy before he leaves the hospital. The young general practitioner is not content until he has done his first case in private practice. And here let me ask, Is it right that every general practitioner, who perhaps has had only a limited experience in surgery or has been watching the operation at some post-graduate

[1] Read before the Manhattan Medical and Surgical Society, April 15, 1899.

school for a few months, should be encouraged to undertake the work of abdominal section and do the work as it is being done to-day? Of course there are exceptions; some men, already well trained in the work, come to the larger cities for the benefit to be derived from seeing operations done by the best operators, with all the improvements that a large city has, and only a large city can command.

On the other hand the hospital interne of any large hospital that has its gynæcological section is well fitted for his work in this line when he has completed his course, and enters the field of private practice. Where could he get a better training than in such a hospital, working directly under the hand and eye of his attending surgeon? The training of an interne under these circumstances is so complete, and yet gradual, that he hardly knows when he has become a good, thorough, and well-trained cœliotomist.

But as to the general practitioner, who is likely to get only an occasional case in his private practice, perhaps in a country town or small city, without competent assistants, without proper hygienic surroundings or all the equipments for rendering the instruments and ligatures aseptic, I regard it a grave error on his part to undertake the work, and on our part to encourage him. Cœliotomy and like operations should be performed only by surgeons trained for the work, with assistants well trained also in their work, in rooms that are made as thoroughly aseptic as it is possible to make them, and with all the modern apparatus and conveniences that the operation may need, and the operation to be done under the best aseptic methods possible. Then, and only then, can we reasonably expect the best results.

Now a few words in regard to preparing the patient for the operation. The heart is examined, and if there is any weakness or lesion strychnine sulph., gr. $\frac{1}{30}$, is given every four hours, with whiskey, ℥ ss. to ℥ i., three times a day. The chest is examined, and if bronchitis is found to exist to any marked degree, the disease is properly treated. Chloroform is ordered at the operation instead of ether. The urine is examined, and if casts or albumin continue to exist after suitable treatment, chloroform is given instead of ether. The same may be given when sugar has been found in the patient's urine. If much sugar or albumin or many casts still continue in the urine after proper treatment, the operation would be postponed.

On the second evening before the operation the patient is given a good cathartic. I usually give two compound cathartic pills, to be followed in the morning by a seidlitz powder, should the bowels not move freely. If the bowels are still stubborn, an enema is given, one-half cup of sweet oil and O i. warm castile soap-suds. On the evening before the operation another dose of cathartics is given, usually a repetition of the first dose, namely, two compound cathartics; this is followed on the same evening by a high enema until the whole lower portion of the bowel is well emptied. The patient is also given a bath and the mons veneris shaved. Then, six hours before the operation, a compress of cheese-cloth saturated with a solution of bichloride, 1 : 5,000, is placed over the abdomen where the incision is to be made, and held there by a binder, and this is not to be removed until the time of operation. In the morning, after the patient has had her movement, a small enema is given to remove any fecal matter that may remain. The urine is drawn by catheter, and then the patient is ready to go into the operating-room. In hospital or private work I always start the anæsthetic in bed, and after the patient is thoroughly under it I remove her to the operating-table, as this is far pleasanter for her. On the operating-table the vagina is well washed out with a solution of green soap, followed by a douch of bichloride 1 : 5,000. The mons veneris and thighs are cleaned in the same manner. Then the uterus is drawn down, the cervix dilated, well curetted, and generally packed with iodoform gauze, which is removed at the end of the operation. The green-soap solution used is made up in the following proportions: Green soap $\frac{1}{3}$, alcohol $\frac{1}{3}$, water $\frac{1}{3}$, glycerin $\frac{1}{12}$.

The cheese-cloth pad is then removed from the abdomen, which is well scrubbed with the solution of green soap followed by ether, then alcohol, then sterilized water, and finally the solution of bichloride 1 : 5,000. The patient is then ready for operation. The patient is placed on the back and the operation is begun. In regard to the incision, I often make it in the median line, but when the abdomen is very thin I make it about one inch from that line to the right or the left, and directly through the rectus muscle; in that way I get a better, firmer wall when the wound unites. The patient is then put in the Trendelenburg position, with the head down and the lower limbs elevated. This removes the intestines from the pelvic cavity, and they slip down under the ribs, and by this method we can easily get at the deeper vessels and ligaments, to tie the arteries. As to the tying of arteries, I always, if possible, use a knot tied in such a manner that it binds itself, and there can be no possibility of the ligature slipping. The only danger is from the contracting of the surrounding tissue when too much has been taken in the bite. The ligature is passed around the tissue twice, and the first half of the knot is tied under the loop, and as it is tightened the loop binds the knot; then an ordinary square knot is tied over this. This method is of great service in tying in deep tissues, where it is almost impossible to keep the first half of the knot from slipping until the square knot has been made.

The ligatures used are of sterilized catgut, No. 3 or 4. Ligatures of silk I have given up, as we have had so much trouble with them; the silk often acting as a foreign body in the abdomen and causing abscess to follow, and later the formation of sinuses, which would not heal in many cases without secondary operation. In some cases the silk would after months eventually work its way up through the sinus and be washed out in douching or have to be pulled out with forceps. I have seen three of these at the Woman's Hospital in which the ligatures were finally washed out of a pelvic sinus with a syringe, and two in which they had ultimately ulcerated through and finally lodged in the bladder, and were removed from the viscus with forceps. The ligatures being thoroughly embedded in a phosphatic deposit, the patient had suffered for some months from cystitis, the result of this foreign substance in the bladder. This danger is obviated by the use of catgut. In selecting the catgut, care must be exercised always to get the best, as there is great difference in it. Nos. 1, 2, 3, and 4 are the most serviceable sizes. One of the best methods of preparing it is as follows: Place the catgut in Squibb's ether, allowing it to remain for one day. Dry it, and place it in a salt-mouth jar filled with absolute alcohol; cover the jar, not too tightly, and place it in the inner compartment of an Arnold's sterilizer, or a common six-quart tin pail, and cover it. Pack towels, cotton, or gauze all around the jar. Then place the covered tin pail in a larger tin pail filled with water, cover the outer pail, and set it over the fire and boil for five hours. At the end of this time remove the catgut with sterilized hands or instruments and cut in convenient lengths. Coil each length and place it in a small glass jar filled with absolute alcohol, cover tightly, and the ligatures are ready for use.

Or should you prefer to use the chromicized catgut, wind the catgut tightly on medium-sized test tubes.

Hold the ends in place with a small elastic band. Place the tube and catgut in a larger test tube filled with chromicizing fluid. Allow it to stand for forty-eight hours; then remove it and dry thoroughly. When dried, unwind it and cut in lengths, coil, and put it in tight glass jars ready for use.

The chromicizing fluid is composed of

| | |
|---|---|
| Potass. bichromat. | 1.05 |
| Carbolic acid | 10.0 |
| Glycerin | 10.0 |
| Distilled water | 480.0 |

The advantage of the chromicized catgut over the simple sterilized gut is that the fluid hardens the catgut so that it will remain longer in the tissues before it is absorbed, lasting from three to six weeks; ordinary catgut will last five days. For this reason, the chromicized catgut is much more to be desired in sewing up or tying of vessels in the deep tissues of the abdomen.

I now come to take up the question of tying off the deep vessels in cases of cœliotomy for hysterectomy, single or double salpingo-oöphorectomy, or the removal of cysts or fibroids of the uterus or surrounding tissue. We have the choice of three methods: First, the use of the ligature; second, electro-cautery with compression; third, simple compression. Which of these three methods is best—best, to control hemorrhage and lessen the liability to shock—best, as being less liable to cause sepsis at a later date? There are two great dangers in the use of ligatures: one is the liability to slip directly after being applied or within forty-eight hours afterward. Do the best we can, we shall once in a while have this accident occur. The second danger is, that they are liable to become and act as a foreign body in the pelvic cavity, causing irritation, pain, and abscess, which ultimately may lead to the formation of an open sinus, to be cured only by a secondary operation for extraction or else by spontaneous ejection through a sinus after allowing the patient to wait during many months of torture.

On the other hand, we have used the ligature so long and been so accustomed to it that when we have been very careful in seeing that it is well tightened on the vessel we can go to bed and feel that we have done all that has been necessary, and can rest accordingly. And to-day the ligature is a grand good thing in its proper place, and there are some places in which it only can be used, and in which the other methods for obliterating vessels (of which I will speak next) cannot be used.

The next method for securing bleeding vessels in the operation of cœliotomy is one that has been pursued by Dr. Skene, of Brooklyn. The method was described some weeks ago in a paper he read before a monthly meeting of the Obstetrical Society of this city, and he also exhibited the instruments and battery. The method consists in the combined use of electro-cautery and compression. The battery is not a large one, and it is connected by insulated wires with a heavy pair of compression forceps, the surface to be heated being confined to one side of one of the jaws of the instrument. The portion of the tissue to be obliterated is firmly seized in the jaws of the forceps, and these jaws are tightened to the third ratchet in the handle, there being four in all. The current is then turned on and allowed to remain one minute, the parts becoming fairly well baked; at the expiration of the minute the jaws are tightened still more until the fourth ratchet is reached, and the current is allowed to remain two minutes more, or three minutes in all. At the expiration of this time the tissue to be removed is cut off with the scissors, and the jaws of the forceps are loosened; the forceps finally is removed gently, the work having been accomplished. This instrument was devised by a young electrician named Pinolet, under Dr. Skene's direction. Pinolet worked long and laboriously at this apparatus, and judging from the results so far accomplished at the Woman's Hospital it certainly has many merits in its favor. On examination of the tissues after the forceps has been removed they seem to be so thoroughly amalgamated and blended together that there is no danger of any after hemorrhage whatever. The only thing necessary is to see that the tissues are well distributed along the jaws of the forceps; as otherwise they will be well baked in some parts and not so well in other parts, thus leaving a chance for some vessel to burst through the stump. But this can be avoided by care, and we have had no trouble of the kind in our sections at the hospital where we have used the instrument more or less all winter.

The next method, and one that I wish particularly to call your attention to, for securing the vessels in cœliotomy is by Tuffier's angiotribe. This instrument was introduced to the medical profession by Dr. Tuffier, of Paris, and though in its present development it is a little heavy and clumsy, still it is about as perfect in its operation as anything we have. It is simply an immense pair of compression forceps, with a groove running along one jaw and a tongue along the other which will allow the jaws to meet approximately all over their closing surface. It has a large hand-crank wheel on a gradual screw at the handle extremity, and on tightening gives an immense pressure of three thousand pounds to the square inch. The tissues to be secured are simply caught between the jaws. The hand-crank wheel having been put in place and the wheel screwed down as tightly as possible, this pressure is maintained three minutes, during which time the diseased tissue is removed with the scissors, and then the jaws are carefully loosened, and the work is done. We have used this method at this hospital a number of times during the last two months, with a perfect result. There have been no shock, no hemorrhage, at the time or following, and no fear of any after irritation or ulceration from the use of ligatures. I can regard it only as the most perfect instrument yet devised for that purpose. After the diseased tissue has been removed with the scissors, the vessels have been secured, and the sponges removed, the patient is given an internal abdominal douche of from one to four gallons of sterilized water, at a temperature of 115° F. An opening for drainage is made in Douglas' cul-de-sac through to the vagina if necessary. For the drainage iodoform gauze is carefully packed into the abdomen and the end left protruding from the vagina. The parts are again carefully examined to see if there are any bleeding points, and if all is secure the abdominal incision is sewed up. In doing this I always use silkworm gut, passing the stitches with a Peaslee needle through the skin, fasciæ, muscle, and peritoneum (being very careful to protect the intestines with a sponge). After the stitches are *in situ*, and before I tie them, I remove the sponges. I start at the upper end of the incision and sew up the fasciæ with a sharp Hagedorn cutting-edge needle, using chromicized catgut No. 1, with the uninterrupted, interlocked stitch, tying the catgut at both ends of the incision. After this is accomplished I have the incision once more washed out with sterilized water. Then, finally, the silkworm stitches are tightened and tied with a single and not double turn of the first half of the knot; then tied square, and the work is done. An aseptic dressing is bound over the incision, the uterine gauze is removed, and the patient is put to bed. At the end of twenty-four hours a cathartic of calomel gr. ss. is given every half-hour until three grains have been administered; this is followed by a saturated solution of magnesia sulph. ℥ ii. every hour until ℥ ss. to ℥ i. has been given, or until the bowels have moved, and

this is later followed by an enema if needed. The silkworm gut stitches are removed on the twelfth day.

37 West Sixty-eighth Street.

## TYPHOID MORTALITY IN TWENTY-FOUR AMERICAN CITIES, 1889–1898.

By F. S. CRUM, Ph.D.,

Newark, N. J.

Two facts of importance are brought clearly to light in the statistics here presented of typhoid mortality in our large American cities. First, the typhoid mortality rates are almost uniformly excessively high, and second, there has been a notable reduction in the rates of most of the cities during the decade under observation.

Table II. shows that Pittsburg had an average annual typhoid mortality rate for the decade of 82 per 100,000 of population, and Brooklyn, at the other extreme, experienced an average annual mortality of 19 per 100,000 of population. In comparison with the typhoid mortality of the large cities of England and Europe, the rates in American cities are exceptionally high. To cite only two examples of foreign cities, London and Berlin, the English metropolis during 1890–1898 had an average annual mortality from typhoid fever of 13 per 100,000 of population, and the German capital during the same period showed the remarkably low rate of 7 per 100,000 of population.

By reference to Table III. it will be seen that in twenty-three of the cities represented the average annual typhoid mortality rate for the latter half of the decade under observation was lower than for the first half, the percentage of reduction ranging from 70.1 per cent. in Newark to 4.7 per cent. in Boston. New

| Denver | 195 | 269 | 88 | 54 | 56 | 44 | 31 | 61 | 40 | 25 | 77 |
| Twenty-four cities | 49 | 58 | 61 | 51 | 41 | 34 | 33 | 32 | 26 | 33 | 41 |

Orleans is the single exception. In that city the last quinquennial periods show a considerably higher typhoid mortality than the first.

In Table I. is presented the actual annual mortality from typhoid in twenty-four American cities.

Table II. shows the annual mortality rates from typhoid fever. The populations upon which the calculations are based were carefully estimated for the intercensal years. The cities in Tables I. and II. are arranged in the order of their size in 1890. With two exceptions the years end December 31st. The figures for Newark are for the years ended June 30th, and those for Louisville are for the years ended August 31st.

Table III. shows the percentage of reduction in the typhoid mortality rates of the twenty-four American cities. The reduced rates are in most instances directly attributable to improvements in the water supplies. Newark and Chicago, which head the list, are typical examples. The Newark water supply was decidedly improved in April, 1892, when the Pequannock river was substituted for the polluted Passaic as a source of water supply. The water supply of Chicago has been gradually improved during the last decade, principally by the extension of the water tunnels and the placing of the supply cribs at points more remote from the lake shore.

TABLE III.—PERCENTAGE OF REDUCTION IN TYPHOID MORTALITY RATES IN TWENTY-FOUR AMERICAN CITIES: 1889–93 TO 1894–98.

| | Rates. | | Percentage of Reduction.[1] |
|---|---|---|---|
| | 1889–93. | 1894–98. | |
| Newark | 61 | 18 | 70.1 |
| Chicago | 99 | 39 | 61.2 |
| Cleveland | 82 | 32 | 61.1 |
| St. Paul | 45 | 18 | 60.0 |
| Denver | 126 | 40 | 58.5 |
| Rochester | 38 | 16 | 57.1 |
| St. Louis | 48 | 23 | 51.9 |
| Milwaukee | 35 | 20 | 43.2 |
| Pittsburg | 107 | 61 | 42.6 |
| Philadelphia | 50 | 37 | 33.3 |
| San Francisco | 43 | 29 | 32.2 |
| Jersey City | 75 | 51 | 31.7 |
| Omaha | 23 | 17 | 27.3 |
| New York | 25 | 18 | 26.9 |
| Providence | 39 | 30 | 24.0 |
| Cincinnati | 52 | 41 | 22.6 |
| Buffalo | 30 | 31 | 19.3 |
| Louisville | 81 | 65 | 19.1 |
| Washington | 82 | 65 | 19.1 |
| Minneapolis | 56 | 46 | 17.6 |
| Baltimore | 45 | 38 | 16.2 |
| Brooklyn | 20 | 17 | 14.8 |
| Boston | 34 | 33 | 4.7 |
| New Orleans | 20 | 47 | + 137.8 |
| Twenty-four cities | 52 | 32 | 38.6 |

[1] The percentages are calculated on the rates carried to one decimal place.

In the above table, Philadelphia shows a reduction in typhoid mortality of 33.3 per cent. The present epidemic would seem to indicate that the reduced mortality was due to no permanent improvement in the conditions of water supply. During the first twenty-five weeks of the present year there were reported seven hundred and seventy-four deaths from typhoid fever in the Quaker City. During the entire year of 1898, which was an exceptionally bad one from the viewpoint of typhoid fatality, there were five hundred and sixty-three deaths from typhoid fever. In view of the facts it is little wonder that the people of that city are at last making herculean efforts to improve their water supply.

In Table IV. is given a summary statement of the typhoid mortality in the twenty-four cities, the cities being arranged in the order of their typhoid mortality, from highest to lowest.

TABLE IV.—A SUMMARY STATEMENT OF THE TYPHOID MORTALITY IN TWENTY-FOUR AMERICAN CITIES DURING THE DECADE 1889–1898.

| | Deaths. | Rates per 100,000 of Population. |
|---|---|---|
| Pittsburg | 2,272 | 82 |
| Denver | 1,006 | 77 |
| Washington | 1,840 | 73 |
| Louisville | 1,280 | 72 |
| Chicago | 8,450 | 65 |
| Jersey City | 1,103 | 62 |
| Cleveland | 1,663 | 54 |
| Minneapolis | 962 | 51 |
| Cincinnati | 1,448 | 46 |
| Philadelphia | 5,186 | 46 |
| Baltimore | 1,966 | 41 |
| Newark | 783 | 38 |
| San Francisco | 1,151 | 35 |
| St. Louis | 1,712 | 35 |
| Buffalo | 1,036 | 35 |
| Providence | 480 | 34 |
| New Orleans | 844 | 34 |
| Boston | 1,604 | 33 |
| St. Paul | 489 | 29 |
| Milwaukee | 625 | 27 |
| Rochester | 400 | 26 |
| New York | 3,533 | 21 |
| Omaha | 295 | 20 |
| Brooklyn | 1,803 | 19 |
| Twenty-four cities | 41,931 | 41 |

In passing, it may be of interest to note that had the Brooklyn average rate (18.6) for the decade prevailed in all of the cities under observation, the total typhoid mortality would have been 19,156 instead of the 41,931 deaths actually recorded. In other words, had the Brooklyn rate prevailed there would have been a saving in this brief period of 22,775 lives.

In conclusion I present a table showing the estimated population, the deaths from typhoid, and the typhoid death rate per 100,000 of population of the twenty-four cities in aggregate for each of the years of the decade, for the two quinquennial periods, and for the entire decade.

TABLE V.—TYPHOID MORTALITY IN TWENTY-FOUR AMERICAN CITIES BY YEARS.

| Years. | Population. | Deaths. | Rate per 100,000. |
|---|---|---|---|
| 1889 | 8,757,556 | 4,271 | 48.8 |
| 1890 | 9,148,645 | 5,267 | 57.6 |
| 1891 | 9,449,741 | 5,743 | 60.8 |
| 1892 | 9,703,186 | 4,943 | 50.6 |
| 1893 | 10,088,493 | 4,088 | 40.5 |
| 1894 | 10,426,154 | 3,567 | 34.2 |
| 1895 | 10,776,855 | 3,571 | 33.1 |
| 1896 | 11,140,833 | 3,545 | 31.8 |
| 1897 | 11,518,802 | 3,045 | 26.4 |
| 1898 | 11,921,287 | 3,891 | 32.6 |
| 1889–93 | 47,207,621 | 24,312 | 51.5 |
| 1894–98 | 55,783,931 | 17,619 | 31.6 |
| 1889–98 | 102,991,552 | 41,931 | 40.7 |

**X-Ray in Lupus.**—A boy of sixteen who had suffered from lupus for five years was treated with rays from a vacuum tube with success. There were seventeen sittings within three months. The hair on the same side of the head was lost, but grew again.—C. T. HOLLAND, *Liverpool Medical and Chirurgical Journal*, January, 1899.

## Progress of Medical Science.

**Important Characteristics Distinguishing the Bacillus of Leprosy from that of Tuberculosis.**—Dr. E. Jeanselme (*Presse Médicale*, April 8th) says that while the bacillus of tuberculosis and that of leprosy possess almost the same form and almost identical reactions, they are nevertheless distinguished by the following important characteristics: (1) In leprosy the number of bacilli infiltrating the tissues is enormous, so great that the mass of bacilli constitutes an important part in the volume of the leprous nodule. (2) The bacilli of leprosy are rarely separated from one another, but almost always exist as colonies, the appearance of which may be likened to a bunch of cigars or to an ear of corn. (3) The bacillus of Hansen cannot be cultivated by any known means. The numerous experiments of Campana, Leloir, Arning, Ducrey, Kanthack, Barcklay, and others have been varied beyond number; all known methods have been tried and all have failed. In several instances in which the effect appeared to be successful, examinations of the culture showed only the bacilli of tuberculosis. (4) The bacillus of Hansen cannot be inoculated in animals. It is impossible to enumerate the various experiments that have been made without result in the endeavor to transmit leprosy to different kinds of animals. (5) The cells that are invaded by the bacillus of Hansen give only a weak reaction. We never find in leprous nodules the grouping which belongs to the elementary tuberculous follicle. (6) The resistance of the bacillus of Hansen to physical and chemical agencies is less than that of the bacillus of Koch. According to the observations of Schaeffer, the bacillus of leprosy, left five or six days in a solution of sulphuric acid, 5 : 100, is no longer colored; while the bacillus of tuberculosis will still retain its coloring matter when it has been subjected to the same treatment for eleven or twelve days. (7) The leper and the tuberculous subject do not react in the same way when submitted to injections of tuberculin. In spite of these differences the analogies are such that we cannot help asking if the bacillus of leprosy and that of tuberculosis are not the issue of a common ancestor. Although it may be impossible to verify this hypothesis it is certain that, at the present time, they represent two distinct species. We are totally ignorant as to the habitat of the bacillus of leprosy when outside the human organism. It has been sought in vain in the soil, even in cemeteries of lepers, and in the foods which has been considered as favorable to the development of leprosy.

**Treatment of Fifty Cases of Infantile Broncho-Pneumonia.**—Dr. E. Vidal (*Gaz. Hebd. de Méd. et de Chir.*, April 13th) reports that out of 50 cases of infantile broncho-pneumonia treated at his private clinic 29 have recovered. Fifteen cases were complicated with measles, 7 were bilateral, and 19 involved the entire lung. Five were under one year, 11 between one and two years, and the remainder between two and six years of age. Three methods of treatment were used: (1) In 11 cases the limbs were enveloped in cotton-wool; cupping, sinapisms, and hypodermatic injections of hydrochlorate of quinine were employed if the temperature was above 39.5 C. The result was 6 deaths and 5 cures. (2) Thirty-three cases were treated by an entirely different method, *i.e.*, cold baths and saline injections to the exclusion of all other medication. Twice daily, and in severe cases three or four times daily, a bath at 28° was given under the personal supervision of the author, lasting four minutes; this was followed by a vigorous massage of all parts of the body with warmed towels. In addition to this 200 to 300 c.c., according to the age, of the following saline solution was given: chloride of sodium, 9 gm.; citrate of caffeine, 1 gm.; water, 1,000 c.c. Of this 40 c.c. was injected under the skin. The result of this method was 21 cured (sixty-three per cent.). (3) Six cases in which on the night following the first application of the treatment indicated under (2) the friends of the patients applied blisters and in three cases refused to return to the prescribed treatment. These three patients died. In the other three cases the families were induced to permit a return to the treatment, and they all resulted in recovery. The points to be studied from these figures are: (1) That the balneo-therapeutic method shows a number of cures larger than has been noted heretofore. It is possible that the series was a particularly fortunate one, but other authorities have obtained analogous results. (2) The baths and the injections have the same therapeutic aim—tonic action on the circulatory system and increased oxidation by means of arterial pressure causing the destruction and elimination of the toxins. Both are the physiological and therapeutical agents *par excellence*. (3) This method of treatment takes time and should have the careful supervision of the physician himself, never being entrusted to the family of the patient. (4) Among certain contraindications to this treatment are a precarious state of the heart and kidneys, and pulmonary tuberculosis. A second deduction is the almost uselessness of blistering in infantile broncho-pneumonia; it is useless, painful, depressing, dangerous, and should be banished from the therapeutics of broncho-pneumonia. If revulsives are required, cupping and hot baths are less disagreeable and far more efficacious.

**Military Surgery.**—Dr. F. A. Abbott (*The Lancet*, January 21, 1899), in an article on the surgery in the Græco-Turkish war, offers the following conclusions: The Roentgen rays should always, if possible, be available at that hospital nearest the front in which the wounds can be first properly examined and dealt with. The electricity should be derived from a secondary battery consisting of separate covered cells charged from the nearest town, a man-of-war or other steamer, or by means of a cycle motor, as has been recently done in the Soudan by Major Battersby. The skiagrams should be taken on Eastman's positive paper which is sufficiently satisfactory for the detection of foreign bodies. The apparatus is of no use on the field, where the detection of bullets can only be an incentive to premature exploration. The less wounds are tampered with before satisfactory surroundings are reached the better. All bullets difficult of access should be removed by a fresh incision and the track ignored. The modern bullet from its greater penetrating power will be much less frequently found in the body than its predecessors; it is practically aseptic and there is no urgency for removal. The hole of entrance is often extremely small. Suppuration is generally due to pieces of clothes carried into the tissues. Superficial septic sinuses should be excised. Wounds of lung by modern bullets run a comparatively favorable course. Small-bore bullets may bore through a bone without causing any line of fracture whatever, and every degree of injury from this up to the most extensive comminution may be met with. Passive movements and massage when possible should be begun early in bullet-wound fractures.

**The Operative Treatment of Hernia.**—Dr. McArdle recently brought before the Royal Academy of Medicine, in Ireland, the subject of the radical cure of hernia, basing his communication on the results in three hundred and forty-two cases. His conclusions were as follows: (1) Without opening up the inguinal

canal no complete operation can be performed. (2) It is a matter of little importance what you do with the hernial sac; it has no bearing on the case; a new sac forms with the greatest readiness if at any point the mid-stratum of the abdominal wall is defective. (3) There is no evidence in favor of opposing the arrangements of nature by displacing the cord. (4) To reconstruct the canal properly, the internal oblique and conjoined tendon should be brought down to Poupart's ligament, not merely to the edge of the external oblique. (5) The complete overlapping of the pillars of the external ring forms a firm basis of support for the healing of the underlying conjoined tendon.

**Foreign Bodies in the Pharynx and Œsophagus.**—From a study of his own cases of œsophagotomy and from a consideration of the reported results, Jones (*Lancet*, May 6, 1899) contends that bodies that have lain for some time and have given rise to symptoms of obstruction, irritation, or dyspnœa should be operated upon without delay. Forcible attempts at extraction by the mouth are to be condemned. Sharp or irregular impacted bodies specially demand œsophagotomy. In certain cases gastrotomy is indicated, and in some a combination of gastrotomy and œsophagotomy. When the wound in the œsophagus is jagged or its walls are inflamed, no stitches should be used. The routine practice when the œsophageal wound is clean-cut is to stitch it up with a continuous suture, care being taken, as in the case of the intestine, not to puncture the mucous coat. Only in exceptional cases, when no danger of suppuration and infection exists, should the external wound be closed. Liquid food may be given by the mouth in about twenty-four hours after operation.

**Secondary Melanotic Sarcoma of the Liver.**—Rolleston (*Lancet*, May 13, 1899) reports a case of melanotic sarcoma of the liver secondary to similar disease of the right eye which had been removed two years previously, and expresses the opinion that malignant melanotic tumors, though usually spoken of as sarcomatous, are not necessarily so; probably a fair proportion are sarcomatous. Secondary melanotic growths in the liver are more often found to follow primary growths of the uveal tract, and reach a larger size than when secondary to cutaneous growths. The hepatic growths are more frequent in men than in women in a proportion of 2.5 to 1. The average age of patients dying with secondary melanotic hepatic growths is 48.7 years. Ascites occurs in more than one-fourth of the cases and jaundice in one-sixth of the collected cases. The urine contains melanin, though when freshly passed it may be in a colorless form (melanogen). Its detection may be of use in diagnosticating a doubtful case of hepatic enlargement.

**A New Method of Reduction in Separation of the Lower Epiphysis of the Femur.**—Hutchinson and Barnard (*Lancet*, May 13, 1899) recommend the following method of reduction in cases of separation of the lower epiphysis of the femur: Under complete anæsthesia an assistant makes steady but strong traction upon the tibia in the line of the limb. This overcomes the upward pull of the quadriceps extensor and brings the epiphysis down to the line of separation. The operator then clasps his hands beneath the lower thigh, and draws it steadily upward, gradually flexing the knee and hip-joint, while the assistant still keeps up the traction on the leg. This causes the epiphysis to move back upon the fractured surface of the diaphysis until it has reached its normal position, and further movement is prevented by the periosteum coming into tight contact with the anterior surface of the femur. A bandage is then applied around the thigh and ankle, fixing the knee at an angle of about 60°. The limb is laid on its outer side on a pillow, and an ice-bag can conveniently rest upon the front of the knee. After fourteen days the limb can be extended, under gas if necessary, and put up in plaster in a position about 30° short of the straight line. The patient can then go about on crutches. The plaster remains on for from a fortnight to three weeks, and a little massage restores the movements of the joint. Four illustrative cases treated by the method described are reported, and the following conclusions are expressed: (1) Separation of the lower epiphysis of the femur is a serious injury, and when compound is attended with a high mortality. (2) In the extended position of the knee, even with an anæsthetic, reduction of the fragment is very difficult if not impossible. (3) When the epiphysis is not reduced the patient is laid up for about three months, and is lame for about six months, while the end of the diaphysis frequently requires removal by operation. Shortening of the limb, and secondary curves in the spine, always follow. (4) Nevertheless, the ultimate result in most cases in which recovery at all takes place is good. The articular surface of the femur gradually grows into a useful position. (5) With the method of full flexion, reduction is always easy, the treatment is short, and it is the rule to obtain perfect movement in the knee without shortening or deformity of the leg.

**Blennorrhagic Peritonitis in Young Girls.**—Including a thesis upon this topic Dr. Rousseau (*Thèse de Bordeaux*) speaks as follows concerning treatment. As prophylactic and for early treatment of the vulvovaginitis permanganate of potassium solution, 1 : 1,000, should be used at the onset, if pulse is good, with antiphlogistics (leeches, poultices with laudanum, ice); then opium; milk diet, acidulated and iced drinks, champagne. When the pulse becomes too frequent a median laparotomy should be performed; a rapid operation to avoid shock, using hot, dry, aseptic towels to keep the intestines warm. The earlier the surgical intervention the greater will be the chances of success.

**Kernig's Sign in Cerebro-Spinal Meningitis.**—Described by a Russian physician and studied in Germany and France, this interesting sign, says Osler, has not attracted the special attention of English and American physicians, though Herrick, at the last meeting of the Association of American Physicians, spoke of its value. It is an old observation that the subjects of protracted meningitis, particularly children, very often lie with the thighs flexed upon the abdomen, and with the legs in a state of partial contracture so that they are with difficulty extended. To test for Kernig's sign the patient should be propped up in the sitting position; then on attempting to extend the leg on the thigh there is contracture of the flexors which prevents the full straightening of the leg. On the other hand, in the recumbent posture the leg can be fully extended. The explanation of the phenomenon, given by Netter in his excellent article on Cerebro-spinal Meningitis in Vol. XVI. of the "Twentieth Century Practice," is as follows: "In consequence of the inflammation of the meninges the roots of the nerves become irritable, and the flexion of the thighs upon the pelvis when the patient is in the sitting posture elongates and consequently stretches the lumbar and sacral roots, and thus increases their irritability. The attempt to extend the knee is insufficient to provoke reflex contracture of the flexures while the patient lies on his back with the thighs extended upon the pelvis, but it does so when he assumes a sitting posture."

# MEDICAL RECORD:

New York, August 12, 1899.

## THE LIABILITIES FOR THE TREATMENT OF PAY PATIENTS IN HOSPITALS.

A RECENT decision of the appellate division of the Supreme Court of this city establishes a very important precedent regarding the liabilities of hospitals for the proper treatment of pay patients. The case on which this ruling was made is that of Ward *vs.* the St. Vincent's Hospital, wherein a female patient occupying a private room, and paying full price therefor, was the victim of the carelessness of a trained nurse in being severely burned by an unprotected hot-water bottle applied after an operation, and while the patient was unconscious from previous etherization. The point of special interest is the fact that all previous decisions regarding the non-liability of hospitals for similar damages are now reversed. Justices Van Brunt, Barrett, Patterson, and Rumsey all concurred in this decision formally rendered by Justice Barrett. The following is the text of the ruling: "Though the defendant is called a charity hospital, it has its pay side, on which side it is in the habit of furnishing private rooms and nurses to well-to-do persons for a full price, thus entering into an express contract. For the breach of that contract the plaintiff is entitled to the same damages as though the action had been for negligence pure and simple, and she is entitled to an adequate compensation for her injuries. The person furnished (Miss Kinney) was not a trained nurse, but a pupil in the defendant's training-school, having studied only nine months of the two years required for the course. It stands to reason that such a misfortune as happened to Miss Ward would have been less likely to occur had she been in the hands of a fully trained nurse. It is for the jury to say whether, in furnishing this careless pupil, of limited experience, the defendant fulfilled its contract obligation to the plaintiff; and if it did not, and injury resulted from the breach of the contract, to award the adequate compensation for such injury." While this ruling is eminently just under the circumstances, it must be clearly understood that it refers to pay patients only, thus absolving from similar penalties the institutions in which patients are treated free. In the former case it is a contract for services for which money is charged, and in the other the moral obligation is involved to do the best for the sufferer on strict Samaritan principles only. Not that there is any difference in the essential duties to be performed, but in the accountability for their performance on a strictly pecuniary basis. Whenever there is a question of money in a transaction, the damages are necessarily decided by a pecuniary standard. The exact contrary of this principle applies to the strictly charitable institutions. When gratuitous service is rendered the recipient, who is the only person benefited thereby, must take them at his own risk. While wilful neglect on the part of beneficiaries is always subject to punishment, the presumption of fair dealing should always weigh in favor of the defendant, who has no real motive for wrong-doing. Pure charity should always be above such suspicion. It simply accepts results without bargaining to control them. Everything is given, and nothing is exacted but the due appreciation of kind offices rendered.

In thus defining the respective rights of the pay and free patient, the line of responsibility in case of malpractice and neglect is very satisfactorily drawn. It is eminently proper that this should be the case, in view of the important issues at stake with all hospital surgeons and physicians. Every one knows how many legal fights have been necessary before this desirable point has been reached. In future cases the latest ruling will effectually prevent any confusing of ideas as to responsibility, and will enable all free hospitals to make a good defence against the frequent and annoying suits brought by designing sharpers, arrant frauds, and shystering lawyers.

## BOVINE TUBERCULOSIS.

BOVINE tuberculosis has been known to stock breeders and owners from time immemorial, but the knowledge of its nature was so vague that no efforts were made either to prevent or cure the disease. The present war against consumption in all its forms has naturally aroused interest in this phase of this subject, and in consequence within the past few years much light has been thrown upon animal tuberculosis and the danger of its communicability to man. It seems more than probable that the risks attending the consumption of meat infected with tubercle bacilli has been considerably exaggerated; if this is not so, what then is the explanation of the fact that although since the middle of the present century meat has been a much more common article of diet than was the case in the first half of 1900, yet within the fifty years just gone by tuberculosis has not only shown no increase but on the contrary has steadily decreased. This happy result is doubtless greatly owing to better sanitation and more healthy hygienic surroundings; but if the meat of infected animals is so deadly as many would have us to believe, it appears reasonable to expect that the disease would be widely spread by it.

There is, however, one form of tuberculosis which has exhibited no apparent decrease. The British Royal Commission, whose report was handed in a few months ago, after referring to the decrease in the mor-

tality rate from tuberculosis makes use of those words: "But whilst this is so, it must be remembered that the rate of mortality from tabes mesenterica, which more than any other represents tuberculosis in infancy, has signally failed to undergo any noteworthy diminution during the very period of sanitary progress which has been associated with such substantial diminution of death from tuberculous affections at all ages in England and Wales, and that this result has coincided in point of time with a large increase in the consumption of milk." Possibly, owing to the greater care taken in many States of this country to insure a pure milk supply, and to the custom of sterilizing milk more frequently practised here, the death rate among infants from abdominal tuberculosis is less than in Great Britain; but despite these precautions tabes mesenterica is a much more fruitful cause of death than it should be.

The probability then stares us in the face that impure milk is the chief cause of this large infant mortality. For some time the identity of the organism found in human tuberculosis and that found in animals was stoutly denied by many, but now most authorities are coming round to the belief that the two bacilli are practically the same. Professor Nocard, of Alfort, France, announces that he has every reason to believe that he has succeeded in transforming the human bacillus into the bovine bacillus. It may then be assumed that milk drawn from the diseased udder of a tuberculous cow may, and in many instances will, be the means of implanting the germs of consumption in those—and especially in young children—who partake of it. Opinions differ, however, as to whether the milk of a tuberculous cow, the udder being unaffected, contains the micro-organism of the disease. In 1895 the Massachusetts Society for Promoting Agriculture is said to have demonstrated beyond a doubt that milk taken from a cow with healthy udders may contain tubercle bacilli.

This being the situation, the question may be fairly asked, "What steps have been taken in this country to guarantee a milk supply free from infection?" According to Dr. Knopf, writing in the *North American Review* of February last, "there are fourteen States which have bovine laws and regulations, and in which circulars are issued for public instruction in regard to tuberculosis in man, viz., California, Colorado, Connecticut, Iowa, Maine, Massachusetts, Michigan, New Jersey, New Hampshire, New York, Pennsylvania, Rhode Island, Virginia, and Wisconsin; two which have bovine laws, but where apparently nothing is done to stop the spread of tuberculosis in man, viz., Minnesota and South Dakota; one which has bovine laws, but which cannot enforce them for lack of funds, and where thus far the board has only issued circulars on the prevention of tuberculosis in man and beast, viz., Tennessee; two, the District of Columbia and Oklahoma Territory, which have a law prohibiting the sale of tuberculous milk, but nothing else concerning tuberculosis in man or beast; eight which issue circulars of instruction concerning tuberculosis in man, but where nothing is done in regard to bovine tuberculosis, viz., Delaware, Indiana, Kentucky, Louisiana, New Mexico Territory, Ohio, Texas, and West Virginia; nine where nothing is done to stop the spread of tuberculosis in either man or beast, viz., Alabama, Arkansas, Maryland, Mississippi, North Carolina, North Dakota, and South Carolina; seven which have no board of health, viz., Georgia, Idaho, Montana, Nebraska, Oregon, Utah, and Wyoming; five from which no answer was received, viz., Florida, Missouri, Nevada, Vermont, and Washington."

It will thus be observed that while fourteen States have adopted and put into force regulations calculated to check the spread of tuberculosis through the agency of milk, the remainder of the States and Territories—excepting the five from which no reply was received—have practically provided no safeguards against this occurrence. Nevertheless, that the large cities are becoming alive to the perils attendant on the existing state of affairs is revealed by the panic that appears to have overtaken Chicago in regard to the danger of contracting tuberculosis from milk taken from infected cows. The governor of Illinois is vigorously interesting himself in the matter, and has declared his intention of backing up the live-stock commissioners with all the power at his command. The commissioners are to be invested with almost arbitrary authority, and a "tuberculosis congress" is shortly to be held in Chicago, at which the whole question will doubtless be discussed in all its bearings.

The fact should always be borne in mind that with animals, as with human beings, tuberculosis does not spread much in those which have plenty of fresh air and light. The health authorities on the part of the general public should therefore insist that the cows from which milk is obtained should be kept in well-lighted and well-ventilated sheds or barns, and should wherever possible be turned out every day in order that these places may be well aired. In those cases in which the udder is infected the only remedy is to slaughter the animals; in other cases in which the beasts react to the tuberculin test isolation should be insisted upon.

The farmer, butcher, and cow-keeper can, of course, effect much by voluntary efforts to protect the public against disease in animals, but unfortunately this course, when it conflicts with their love of gain, is not likely to be followed. If, however, as with the inhabitants of Chicago, the public are thoroughly awakened to the danger of tuberculous milk, and refuse to buy the fluid unless guaranteed pure, the owners of cows will quickly find it to their interest to supply such an article. In the words of Mr. W. Hunting: "By man's ignorance the disease has been allowed to spread; by man's knowledge it can be controlled."

**A Boy's Curious Impulse.**—A boy was recently arrested in this city for spitting on women's skirts, and was fined in the police court for disorderly conduct. He has several times been apprehended for the same cause, and appears to derive gratification from indulgence in this impulse.

## DOMESTIC HYGIENE IN AMERICA AND GREAT BRITAIN.

At the Women's International Convention, held recently in London, a woman journalist from New York read a paper before the convention in which she declared her conviction that as a housewife the American woman was far superior to her British sister. Nor was this declaration of opinion made on idle premises, nor supported by insufficient testimony, but it professed to be a sober and well-matured judgment, based upon a varied experience of domestic life on both continents. Perhaps the remarks of the New York woman in regard to the lack of proper domestic sanitation, and her aspersions on the comfort of the guest chamber—especially as to the comparative cleanliness of the bedclothes—in the houses of well-to-do British matrons will be regarded by them as the unkindest cut of all. If there is one thing upon which the Englishwoman prides herself more than upon another, it is with respect to her super-excellent qualities as the manager of her home.

The English *Sanitary Record* takes up the cudgels in defence of the maligned British housewife, and strongly denies that in the matter of sanitation, or so far as domestic hygiene generally is concerned, the house controlled by the Englishwoman is one whit inferior to that of an American woman of the same class, but contends that there is no appreciable difference in their methods of management; and it then goes on to say: "The greatest difficulty our health officers experience is in getting the poorer people of the country to pay attention to the details of a healthy home. The lower you go down in the social scale the greater the evil. And we are bound to say this obliviousness to the elementary principles of health is more apparent in women than men. A journey has only to be made through some of the thickly populated thoroughfares of our great cities to realize this truth; for in many of them women may be seen standing about in a condition of dirt and filth which is only too true an index of the state of their homes. To alter this condition of things almost necessitates an entire change in the very nature of our poor people."

The New York woman journalist may be right or she may be wrong, but so far as the condition of the poor in large cities is concerned, it would appear that the remarks of *The Sanitary Record* might apply to America with as much truth as to England. The remedy lies in educating the people themselves, and thus awakening them to a sense of their danger and to the healthfulness of cleanliness.

---

**The Uses of Germs in the Extortion of Money.**—A medical student in Gratz, Austria, was recently arrested for attempting to extort money from a rich widow under threat of scattering a number of pathogenic bacteria in her room and over her clothes. Several test-tubes containing cultures of cholera, typhoid, and tetanus bacilli, which he had abstracted from the bacteriological laboratory, were found upon him when he was arrested.

## News of the Week.

**The Plague** has reappeared at Calcutta, and some apprehension is felt that it may become epidemic, the sanitary condition of the native quarters not being above suspicion. In the speech from the throne on the occasion of the prorogation of the British parliament on August 7th, it is stated that the plague in India, though still confined to the areas affected during the winter, shows no sign of abatement.

**A Statue of the Late Dr. Pepper** has been erected in the grounds of the University of Pennsylvania at Spruce and Thirty-fourth streets, Philadelphia. It will be unveiled with appropriate exercises early in the autumn.

**Dr. John M. Holt.**—At the recent examination for assistant surgeons in the Marine-Hospital service, Dr. John Milton Holt, of Brooklyn, late assistant physician to the Manhattan State Hospital, successfully met the requirements and has reported for duty at the United States Marine Hospital, St. Louis, Mo.

**A Convert to Christian Science.**—Dr. A. L. Hunt, of Kansas City, who is said by a correspondent of the New York *Times* to have been a successful practising physician for fourteen years, is reported to have retired from material medicine and to have become an advocate of the Christian Science non-treatment of internal maladies. Dr. Hunt is a graduate of the University Medical College of Kansas City in the class of 1885.

**Yellow Fever in Tropical America.**—The yellow fever at Vera Cruz is reported to be diminishing, the deaths during the last week in July having been only seventeen, as against seventy-eight in the last week of June. At Panama one case of the disease was reported on August 4th, although on July 29th the epidemic was officially declared at an end. Up to that date there had been eighty-eight cases, forty-five of which resulted fatally. Two cases with one death occurred recently at Santiago, but there is no fear of a renewed outbreak. The first case of yellow fever among the troops in Havana occurred on August 7th at La Punta barracks.

**Famine and Disease in Russia.**—The accounts which come from various sources of the terrible famine now raging in the eastern provinces of Russia show a very distressing state of affairs. The lack of crops in Russia, caused by the long-continued drought, has affected an immense tract of land, and the peasants are, in consequence, literally dying by thousands. In addition to the famine, the attendant diseases, typhus and relapsing fevers and scurvy, are causing great havoc. The *Novoe Vremya* says that the harvest this year will be even worse than the one last year, and nothing but the most extensive charity will save entire provinces from extinction. The Russians themselves are giving liberally, and the government has ordered the undertaking of several works of pub-

lic utility in order to give employment to the destitute. Large amounts of supplies and money have been sent from England, and recently a committee has been formed in New York to solicit contributions in aid of the sufferers.

**The Charité Hospital of Berlin** is being demolished and will be replaced by a structure built in accordance with the latest sanitary ideas. The new building will have a large amphitheatre with seats for two hundred and fifty students, post-mortem rooms, rooms for microscopical work, and a special wing for the pathological museum.

**Another Tuberculosis Cure.**—In a report published in the United States Consular Reports, the United States commercial agent at Roubaix, France, describes a method of treatment of pulmonary tuberculosis claimed to have been devised by a Dr. Mendel. It consists in intratracheal injections of a solution of eucalyptus, thymol, and cinnamic acid in olive oil. Dr. Mendel says he has treated sixteen patients suffering from tuberculosis and two with simple bronchitis. In all these cases he has noted, after a treatment lasting one or two weeks, a lessening or complete cessation of the cough and expectoration, as well as a return of sleep, appetite, and strength.

**Yellow-Fever Inoculations** —The case of Mr. Lackey, recently treated for yellow fever at the New York Quarantine by means of serum, was apparently not the first case of such treatment in this country. Dr. P. E. Archinard, of New Orleans, treated twelve patients during the fall of 1898 with Sanarelli serum. A belated report of these cases is published in *The New Orleans Medical and Surgical Journal* for August, 1899. Of the twelve patients treated, four died and eight recovered, but the latter, Dr. Archinard believes, would have recovered without treatment, and he concludes that the agent showed no curative powers whatsoever, none of the important and dangerous symptoms of the disease having been in any way mitigated or prevented by its administration. Dr. Doty is reported to have made arrangements to have a test of the yellow-fever serum among patients suffering from that disease at Bahia, Brazil, where considerable yellow fever has been reported.

**Inhumanity of Strikers.**—We mentioned recently the brutal attack by street-railway strikers or their sympathizers upon a physician of this city solely because he had dressed the wounds of a so-called "scab," and now the story of conduct equally inhuman comes from Cleveland. The strikers on the street-railway lines in that city, in the hope of compelling acquiescence in their demands, organized a boycott on all who dared ride in the cars, and tradesmen were forbidden to sell anything to or to have dealings of any kind with those who disobeyed the strikers' commands. In several instances, it is said, druggists refused to compound prescriptions, although the remedies were urgently needed, because the physicians who wrote them had been known to ride in the cars while visiting their patients. It is to be hoped that the physicians of Cleveland will know how to show their appreciation of such cowardly and inhuman conduct.

**Fire in a Soldiers' Hospital.**—Fire broke out one night last week in the kitchen of the United States Hospital on the government reservation at Fort Hamilton, New York harbor. It was discovered by a sentry, who sent out an alarm, but before the firemen arrived the fire was put out. There were fourteen patients in the hospital, who were removed promptly without accident.

**Yellow Fever at Hampton.**—The health officers have quickly gained control of the yellow-fever invasion of the Soldiers' Home at Hampton, but one new case, up to the present writing, having been reported in the institution since Thursday of last week. The scare to which the outbreak gave rise in Norfolk has subsided, and most of the refugees have returned to their homes. Dr. A. H. Doty, health officer of this port, has denied the report that yellow fever was taken to Hampton by a man who passed New York quarantine without examination. Since May 1st every passenger arriving at this station on a vessel from a Cuban port has been held at quarantine for five days from the time of embarkation, unless he has presented an immune certificate issued by a representative of the Marine-Hospital service at the port of departure. The baggage of arrivals from Cuban ports is also disinfected.

**Consolidation of Veterinary Colleges.**—The two veterinary schools in this city, the American Veterinary College and the New York College of Veterinary Surgeons, have been incorporated into the New York University. The new school will bear the name of the New York American Veterinary College, and will be on a like footing with the other six schools of the university. The college building is the one formerly occupied by the American Veterinary College on West Fifty-fourth Street. The two veterinary hospitals formerly used by the respective schools will be continued, affording abundant material for clinical instruction. New York University hereafter will grant the degree of doctor of veterinary surgery to all students entering its college who meet the regents' requirements as to preliminary education, and who pursue successfully the three years' course of study. In order to enter the school a student must have obtained forty-eight counts in a regents' examination, this being considered the equivalent of a high-school education. Dr. Alexander F. Liautard has been appointed dean of the college. Drs. Edward K. Dunham and William H. Park, of the New York University Medical College, have been appointed to the chairs of comparative pathology and bacteriology respectively.

**Fatal Christian Science in Chicago.**—A woman died of septicæmia a few days ago in a hospital in Chicago, after having been attended by a notorious "healer" of that city. The hospital physicians attributed the death directly to the neglect of treatment, and an investigation of the case has been undertaken by the State board of health. The healer said that her

victim's death was due to the fact that the woman did not believe sufficiently in "divine healing." The healer explained her inability to obtain a license by the fact that "the regulations of the law are not in accord with the faith of divine healing." It is reported that when the Illinois State board of health meets in September, the physicians of the whole State will memorialize the body to begin prosecuting every one who practises according to the tenets of Christian Science. The followers of this belief smile at the threat, and say that they are strong enough in the State to defeat any modification of the present law in case it is found not to be comprehensive enough to deal with their crimes; or in case any convictions are obtained under it as it now stands, they will have it amended so as to legalize their murderous but lucrative inactivity.

**The Health of the Pope.**—Dr. Lapponi, physician to the Pope, said in a recent interview that his illustrious patient was in better health and strength than for several years past. His improvement dates from the early spring, when a cyst which had caused him much annoyance was removed from his leg.

**The New Jefferson Medical College.**—The new buildings and laboratories of the Jefferson Medical College, Philadelphia, will be opened with appropriate exercises on Monday evening, October 2d. Dr. Thomas Addis Emmet, of New York, of the class of 1850, will preside, and the introductory address will be delivered by Dr. Phineas S. Conner, of Cincinnati, a graduate in the class of 1861.

**An Epidemic of Infantile Paralysis.**—The occurrence of acute anterior poliomyelitis in epidemic form among little children is rare, but Poughkeepsie, N. Y., seems to be having such a visitation at the present time. Over fifty cases in children, the great majority of whom are under five years of age, have exhibited all the symptoms of sudden spinal paralysis. Dr. Henry D. Chapin, of this city, was requested by Dr. D. M. Sheedy to examine some of the cases under his care. Dr. Chapin regarded the cases as poliomyelitis. An examination of the blood has proved to be negative.

**Health Work in New York City.**—According to the report of the board of health for the first quarter of this year, the inspectors of the sanitary bureau made 451,781 inspections and reinspections, and returned 29,979 complaints. The division of food inspection reported a total of 268,521 inspections, and 1,402,773 pounds of milk, fruit and vegetables, meat and fish were condemned. Inspections made by the sanitary police numbered 88,048. There were reported 9,377 cases of contagious diseases; measles, diphtheria, and scarlet fever comprising about two-thirds of the total. The number of rooms fumigated or disinfected was 13,497; 15,262 pieces of goods were disinfected, and 1,330 destroyed. Antitoxin was administered in 171 diphtheria cases, in 110 of which a cure was obtained. In all 814 schools were inspected, the total number of visits being 28,892. The average of attendance of scholars was 389,304; of these, 41,043 were examined, the examinations resulting in the temporary or permanent exclusion of 2,536 children. The deaths reported during the quarter were: Manhattan 9,420, death rate 19.29; Bronx 936, death rate 22.89 (mainly due to deaths in institutions of inmates transferred from Manhattan); Brooklyn 5,422, death rate 17.61; Queens 608, death rate 18.13; Richmond 331, death rate 19.68. The deaths in the entire city numbered 16,718, giving a rate of mortality of 18.84.

**A Latin-American Medical Congress** will be held at Santiago de Chili in the autumn of 1900. The initiative was taken by the government of Chili, which has invited all the medical bodies and governments of Latin America to send delegates.

**Smallpox in New York State.**—A case of smallpox has been discovered at Cato, Cayuga County, another at Seneca Falls, and three at Niagara Falls. It is feared that there have been other cases which have escaped recognition. During the prevalence of the disease in the State last winter much difficulty was experienced by the health officers in locating the cases in consequence of the frequent mistakes in diagnosis, the disease being regarded as simple chickenpox and so not being reported to the State board of health.

**Pennsylvania State Medical Examinations.**—At the examinations recently held fifty-two (12.2 per cent.) of four hundred and twenty-five candidates for license to practise medicine in the State of Pennsylvania failed.

**The Status of Charlatans in Indiana.**—The Indiana State board of medical examiners recently obtained from the attorney-general an opinion as to the standing of osteopaths, Christian Scientists, and others of the ilk under the present medical law. He states that it is a violation of the law for an unlicensed person to attempt the cure or relief of disease, injury, or deformity, especially when any fee is charged for such service. It is obvious, he says, that the non-treatment of a disease requiring treatment may be as injurious as the administering of erroneous treatment or remedies, and it is the intent of the law to protect the public from the evil of non-treatment or non-action as fully as from that of wrong treatment. "In so far, then, as Christian Scientists, faith curists, mental healers, and metaphysical medicators advertise themselves as physicians and accept fees for treating diseases by silent or other forms of prayer, or by moral advice, or by profound thought, or by absolute non-action, they unquestionably violate the law." On the other hand, osteopaths and magnetic healers who abstain from claiming to be doctors and from advising treatment, and simply administer massage, cannot be prevented from doing so whenever they please, and there is nothing in the law which requires masseurs to be licensed. One who administers massage, whether recommended by a physician or voluntarily sought by an afflicted person, is at liberty to charge for his services whatever he deems them to be worth, but such a person must not claim to be a physician or to possess the ability to cure disease.

**Smallpox in the South.**—Smallpox prevails to a considerable extent and is increasing in the border towns in Tennessee, Kentucky, and Virginia. A

quarantine has been established against several of the infected towns.

**Foreign Students in Germany.**—There are twenty-two hundred and eighty-four foreign students at the German universities this summer, including three hundred Americans. Only a few of these are medical students, although proportionately their number is fairly great.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending August 5, 1899. July 31st.—Assistant Surgeon C. A. Crawford detached from the *Wabash* and ordered to the *Massachusetts*; Assistant Surgeon E. J. Grow detached from the *Massachusetts* and ordered to the *New Orleans* immediately; Assistant Surgeon M. S. Elliott detached from the marine examining-board, August 2d, and ordered to temporary duty at the marine recruiting rendezvous, New York, during leave of Passed Assistant Surgeon E. S. Bogert; upon completion of this duty, directed to wait orders. August 1st.—Surgeon C. G. Herndon ordered to the museum of hygiene for temporary duty; Passed Assistant Surgeon J. C. Rosenbleuth detached from the *Vermont* and ordered to the *Nashville;* Assistant Surgeon F. L. Pleadwell detached from the *Nashville* and ordered to the bureau of medicine and surgery.

**A Pension for Mrs. Kanthack.**—The widow of the late Dr. A. A. Kanthack, formerly professor of pathology in the University of Cambridge, has been placed on the civil list for a pension of £60 a year, "in consideration of eminent services rendered to science" by her late husband.

**A Definition of a Medical College in Good Standing.**—A resolution adopted on July 11th by the Illinois State board of health defined the phrase in the State medical practice law "medical college or institution in good standing" to include only "legally organized, properly conducted medical institutions, having a sufficient and competent corps of instructors, and ample facilities for teaching, dissections, ambulatory and hospital clinics, which conform to the requirements relative to the preliminary education of matriculates, the course and period of study, the number, character and length of lecture terms, the duration of attendance on hospital and clinical instruction, which obtain in the majority of medical colleges in the United States" The board also resolved that it would not consider in good standing, after January 1, 1900, any medical institution which does not require of all students (excepting graduates of reputable colleges of arts and sciences, or of reputable colleges of dentistry, pharmacy, or veterinary medicine, to whom one year's advance standing may be granted) as a condition of graduation, an attendance on four full courses of lectures of at least six months each, in four separate years, no two courses commencing or ending in the same calendar year of time. And it further declared that no medical college issuing a catalogue or announcement in which are contained misrepresentations respecting its teaching, clinical or hospital facilities, its faculty or its courses of study, or false representations as to the number of students matriculated or in attendance, will be regarded as in good standing.

**Chiropodists for the Army.**—Sir John Colomb, in the House of Commons, advocates the regular appointment of chiropodists in the British Army. This is certainly not a bad idea, for the care of the feet is one of the most important factors in a campaign where much marching is to be done.

**Obituary Notes.**—Dr. Irving C. Schureman died on Sunday at his home in Toms River, N. J., of heart disease. He was fifty-nine years of age, and had practised medicine at Toms River for thirty years. He was a graduate of the Albany Medical College in 1869. He is survived by a widow and four children. —Dr. Charles W. Adams, of Kansas City, who was one of the founders of the University Medical College of that city, and was professor of gynæcology at that institution, and for five years dean of the faculty, died on August 3d from an overdose of chloral. He was graduated from the College of Physicians and Surgeons in this city in the class of 1879.—Dr. William W. Parker died at his residence in Richmond, Va., on August 3d, aged seventy-five years. He was a graduate of the Medical College of Virginia in the class of 1848. During the civil war he commanded the celebrated Parker Battery, of the Confederate service. He was captain, surgeon, and chaplain of his battery, and the man of whom Gen. Stephen D. Lee said: "He could outcut, outpray, and outfight any man in the Confederate Army."—Dr. John M. Fletcher, of Belfast, Me., died at his home in that city on August 7th, at the age of seventy-three years. He was an ex-mayor of the city and ex-treasurer of Waldo County. He was a graduate of the Medical School of Maine, Bowdoin College, in the class of 1868.—Dr. Charles Jennings, of this city, died on July 2d at Bellevue Hospital. He was addicted to the immoderate use of alcohol and various narcotic drugs, and his death occurred in a stupor caused by ether. He was found insensible on the street and taken to the hospital, where he died unrecognized and was buried in Potter's Field. Recently his relatives in a neighboring city learned of his death, and discovering where the body lay had it taken to his former home for burial. Dr. Jennings was at one time on the house staff of Charity Hospital and also of the Orthopædic Hospital in this city. He was afterward a ship's surgeon, and during the Spanish war was for a time an acting assistant surgeon in the army.—Dr. James F. Judd died of erysipelas at Philadelphia on August 5th, at the age of thirty-eight years. He was a native of England, and was graduated from the Jefferson Medical College in 1897.—Dr. H. Stangewald, of Honolulu, died at his home in Nuuanu Valley on June 1st, after an illness of about two months. He was born in Dresden in 1829, and was graduated from the University of Vienna. He had practised in Hawaii about forty years. He was called by the natives "Kauka Minukeole," which has the flattering interpretation of "the doctor who does not take a minute to cure."

# Reviews and Notices.

HAY FEVER, AND ITS SUCCESSFUL TREATMENT. By W. C. HOLLOPETER, A.M., M.D., Clinical Professor of Pediatrics in the Medico-Chirurgical College of Philadelphia; Physician to the Methodist Episcopal Hospital; Pediatrist to the Medico-Chirurgical Hospital and to St. Joseph's Hospital; Fellow of the American Academy of Medicine, etc. Second edition, revised and enlarged. Philadelphia: P. Blakiston's Son & Co. 1899.

THE first edition of this little book was reviewed in these columns only one year ago. Taking advantage of the call for a second edition, the author has added some new matter on the special treatment of each of the various types of hay fever. Some additions have also been made in the bibliography of works appearing during 1898 and the first four months of 1899. Dr. Hollopeter writes with the quiet assurance of one who describes a method that he knows by experience to be efficacious in the relief of this most distressing malady.

TRANSACTIONS OF THE LOUISIANA STATE MEDICAL SOCIETY, at its Nineteenth Annual Session, Held at New Orleans, La., May 10, 11, and 12, 1898.

IT has frequently been remarked that a paper published only in a volume of transactions is practically buried, but we have never seen any so effectually and finally entombed as the papers here. A very careful search has failed to discover either index or table of contents, and there are even no running page-heads. Any one wishing to see what papers were read at the meeting must therefore thumb all the leaves of a three-hundred-page book before his legitimate curiosity is gratified. The reviewer confesses to a fair degree of curiosity, but it balked at this; and any reader who desires to know what was accomplished at this doubtless very satisfactory meeting must wet his thumb and do the work himself.

SHALL WE DRINK WINE? A Physician's Study of the Alcohol Question. By DR. JOHN MADDEN, Professor of Physiology in the Wisconsin College of Physicians and Surgeons. Milwaukee: Press of Owen & Weihbrecht Co. 1899.

THIS is a calm, dignified, and temperate discussion of the alcohol question, which can profitably be read by the physician, the moralist, the sociologist, the prohibitionist, and the habitual consumer of alcoholic beverages. There is little in the way of diatribe to arouse a spirit of opposition in the moderate, occasional drinker, yet the writer is a declared enemy of alcohol, in the increasing consumption of which he believes lies a serious menace to civilization. The work treats of the composition of the more commonly used alcoholic beverages, the value of alcohol as a food and a stimulant, and the general and special pathology of alcoholism; then the attitude of the medical profession toward alcohol is discussed, the ground being taken that alcohol might be blotted out of the list of remedies employed in the treatment of disease, without detriment; and, finally, a chapter is devoted to the best means of combating the alcohol evil.

TEXT-BOOK OF OPHTHALMOLOGY. By DR. ERNEST FUCHS, Professor of Ophthalmology in the University of Vienna. Authorized Translation, revised from the seventh enlarged and improved German edition, by A. DUANE, M.D., Assistant Surgeon to the Ophthalmic and Aural Institute, New York. New York: D. Appleton & Co. 1899.

THIS work, upon its appearance about a decade ago, at once took high rank in ophthalmological literature, and has maintained it through the successive German editions which have been issued at intervals of but little over a year. The first English translation, which was published seven years ago, was well received by English-speaking physicians, and we venture to predict an even more cordial welcome for this second American edition. It is a distinct improvement over the first, in that, while all the excellence of the first edition as regards pathology is preserved, the sections on therapeutics are amplified and improved, thus enhancing greatly the practical utility of the work. The translator has also performed the work of editor, and has done it most creditably, his notes and additions increasing the value of the book as a guide to American ophthalmologists. The illustrations, of which there are two hundred and seventy-seven, are as a rule very good.

TRANSACTIONS OF THE NEW YORK STATE MEDICAL ASSOCIATION FOR 1898. Vol. XV. Edited for the Association by M. C. O'BRIEN, M.D. Published by the Association. Rumford Press, Concord, N. H.

THIS well-printed volume of nearly eight hundred pages opens with an address by the president, Dr. F. H. Wiggin, giving a résumé of the year. Then follow somewhere in the neighborhood of fifty able papers, reflecting the high standard of scientific achievement aimed at by the association. Reports, memoirs, lists of members, and lists of those deceased make the remainder of a very creditable showing.

PULMONARY TUBERCULOSIS: Its Modern Prophylaxis and the Treatment in Special Institutions and at Home. Alvarenga Prize Essay of the College of Physicians of Philadelphia for the year 1898, revised and enlarged. By S. A. KNOPF, M.D. (Paris and Bellevue, N. Y.), Physician to the Lung Department of the New York Throat and Nose Hospital; former Assistant Physician to Professor Dettweiler, Falkenstein Sanatorium, Germany; Vice-President of the Pennsylvania Society for the Prevention of Tuberculosis; Fellow of the American Academy of Medicine; Laureate of the Academy of Medicine of Paris, etc. With descriptions and illustrations of the most important sanatoria of Europe, the United States, and Canada. Philadelphia: P. Blakiston's Son & Co. 1899.

THE spirit which animates the author throughout the three hundred and fifty pages of this admirable work is exemplified in the motto of the introductory section, which is the oft-quoted but not always credited sentence of Pasteur: "It is in the power of man to cause all parasitic diseases to disappear from the world." Dr. Knopf believes in the curability of tuberculosis in the individual, and he appears also to cherish the hope that the disease may some day be annihilated; but a perusal of his book and a consideration of the enormous social changes therein outlined, which must take place before such a consummation can be effected, leave the reader appalled at the magnitude of the task of actually causing the disease to disappear from the world. That, however, is a question that does not immediately concern us, for it is certain that no man living will see the "white plague" wiped out, and our present task is to prevent the disease in the predisposed and to cure it in those already attacked, whose own life is directly threatened and who are also a menace to the well about them. While Dr. Knopf's book is a treatise on the prevention and cure of pulmonary tuberculosis, it is more, for it is the most complete treatise, if not the first, on the sanatorium treatment of consumption, in the English language. Indeed, we know of no work in any language which contains more detailed information on this branch of tuberculo-therapeutics than the one before us.

We cannot here review at length all the interesting points touched upon by the author, such as the use of masks to prevent the expulsion of infected particles of sputum during coughing or even speaking, the numerous and often curious modes of infection, the directions for dress and personal hygiene of tuberculous patients, the results obtained by adding tropon to the dietary, the condemnation of tuberculin treatment and of orrhotherapy in general in tuberculosis, etc. All these and many other subjects are discussed sensibly and fairly, though not necessarily impartially, for the author has positive views on many controverted points, which he does not hesitate to express and to defend with cogent reasoning. The method of treatment to which decided preference is given is the hygienic and dietetic, either in a sanatorium or under medical supervision at home. More than forty sanatoria, hospitals, and homes for consumptives are here pictured, and the therapeutic and hygienic measures employed in each are described from personal observation, the author having visited for this purpose most of the institutions in this country and Europe. Not the least interesting and suggestive chapter in the book is the one devoted to a description of an ideal sanatorium, in which Dr. Knopf has embodied his own ideas as to what is needed in an institution of this sort, in both exterior arrangement and internal regulation. After the brief and fragmentary description here given of this

most timely book, we need not recommend it to physicians and sanitarians interested in the individual and social prophylaxis of tuberculosis, for all such will find it indispensable. We regret that the book, which is well printed and well bound, should be marred by the insertion of the publishers' catalogue. It is an insult to the purchaser of a bound book to force him to buy along with it, and keep in permanent form on his shelves, some fifteen or twenty pages of advertisements.

THE HYGIENE OF THE MOUTH: A Guide to the Prevention and Control of Dental Diseases. By R. DENISON PEDLEY, F.R.C.S. Ed., L.D.S. Eng., Dental Surgeon to the Evelina Hospital for Sick Children, Southwark, London. London: J. P. Segg & Co. Philadelphia: The S. S. White Dental Manufacturing Company.

THIS small work of less than a hundred pages, printed in large type on thick paper, and containing numerous woodcuts, gives rules for keeping the mouth, and especially the teeth, in a healthy state. Especial attention is given to the care of the mouth in childhood, since much ill-health in after life can be traced back to neglected teeth. Such a work should interest physicians as well as others, but appears to be written more for the guidance of parents, managers of institutions, and the laity in general.

A CLASS-BOOK OF (ELEMENTARY) PRACTICAL PHYSIOLOGY, including Histology, Chemical and Experimental Physiology. By DE BURGH BIRCH, M.D., C.M., F.R.S.E., Professor of Physiology in the Yorkshire College of the Victoria University; Examiner in Victoria University; Additional Examiner in the Edinburgh University. Philadelphia: P. Blakiston's Son & Co. 1899.

BASED upon notes for student's use, the author presents, in divided lessons, concise instructions for practical work in laboratory and class room. The simplification of the whole subject, and especially of instrumental appliances, has been aimed at. In part, the work is illustrated, but pictures have been intentionally omitted from the section on histology, so that in reproducing objects the student may not be influenced by the published pictures he has seen. There are over two hundred and seventy pages.

PROGRESSIVE MEDICINE, VOL. II. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Science. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Octavo, handsomely bound in cloth: 472 pages, 56 illustrations and 3 full page-plates. Philadelphia and New York Lea Brothers & Co. June, 1899.

THIS section of the year book gives us the surgery of the abdomen, including hernia, gynæcology, diseases of the blood, diathetic and metabolic disorders; diseases of the spleen, thyroid gland, and lymphatic system; and ophthalmology. The writers for the whole set include, among others, Baker of Michigan, Belfield of Illinois, Blackader of Canada, Bloodgood of Maryland, Coley of New York, Ewart of London, Gerrish of Maine, Randolph of Baltimore, Stockton of Buffalo, and Turner of Edinburgh. Most of the reports are in an easy, flowing, conversational style. Besides Coley, already mentioned, who fathers the first subject, we have John G. Clark, of Baltimore, managing the gynæcology; Alfred Stengel, diseases of the blood; and Edward Jackson, ophthalmology. There are but few illustrations. While the material for the chapters before us has been laboriously worked over and well presented, the objection advanced seems to be valid, that for a year book one has to wait until too late in the year for the completed work to make it of the greatest value as a means of reference.

TRAITÉ DE MÉDECINE ET DE THÉRAPEUTIQUE. Par P. BROUARDEL et A. GILBERT. Tome Sixième: Maladies du cœur, des artères, de l'aorte, des veines, du système lymphatique, et du sang. Paris: Librairie J.-B. Baillière et fils. 1899.

THE contributions to this the sixth volume of this system of medicine include Drs. Merklen, Roger, Gouget, Boinet, Widal, Bezançon, and Parmentier, out of the eighty writers in the list of the completed work. The volume is quite a large one, reaching just one thousand pages. The subject of cardiac affections has been considered from its many different sides, and modern views have been freely reflected in Dr. Merklen's chapter, which covers four hundred and fifty-six pages. Diseases of the arteries, which carries us over to page 568, written by Roger and Gouget, gives an excellent résumé of all that is known on the subject. It is perhaps Dr. Parmentier's elaborate presentation of diseases of the blood which reflects more than the other chapters the many changes and advances which have taken place of late years. The work is very elaborately written, but without illustrations.

INTERNATIONAL CLINICS. A Quarterly of Clinical Lectures on Medicine, Neurology, Surgery, Gynæcology and Obstetrics, Ophthalmology, Laryngology, Pharyngology, Rhinology, Otology, and Dermatology, and Specially Prepared Articles on Treatment and Drugs By Professors and lecturers in the leading medical colleges of the United States, Germany, Austria, France, Great Britain, and Canada. Edited by JUDSON DALAND, M.D., University of Pennsylvania, Philadelphia, Instructor in Clinical Medicine and Lecturer on Physical Diagnosis in the University of Pennsylvania, Assistant Physician to the Hospital of the University of Pennsylvania, etc.; Fellow of the College of Physicians of Philadelphia. Volume I., ninth series. Octavo, pp. x., 303. Philadelphia: J. B. Lippincott Co. 1899.

THIS periodical continues to keep its usual standard. Among the contributors to the present volume are noticed Ashhurst, Baginsky, Eulenburg, Fournier, Hamilton, Kirstein, Lesser, Skene, Wassermann, and H. C. Wood. Other names equally well known on both sides of the Atlantic appear in the list. To those at a distance from centres of medical education these lectures are invaluable in keeping their possessor abreast of the times, and it is often a pleasure rather than a task to take in the information to be found in the "Clinics" in this manner.

SELECTED PAPERS ON STONE, PROSTATE, AND OTHER URINARY DISORDERS. By REGINALD HARRISON, F.R.C.S., Surgeon to St. Peter's Hospital, etc. London: J. and A. Churchill. 1899.

WE have in this book a collection of papers, some of which have appeared in print before, and are now published in book form. They form a series of interesting talks by an experienced surgeon upon the surgery of the urinary organs, and in some of them there is valuable information on points still undecided. The author thinks that "vasectomy" has a useful future in a certain number of selected cases, and has himself had good results, when the enlargement of the prostate was not too great or too much limited to the centre of the organ, and when the patients were otherwise in a fairly operable condition. The author is rightly a strong believer in the efficacy of an external urethrotomy for drainage in preventing septic processes, when a deep internal urethrotomy is done. All the papers are worth reading, some more so than others.

OCULAR THERAPEUTICS FOR PHYSICIANS AND STUDENTS. By F. W. MAX OHLEMANN, M.D., Late Assistant Physician in the Ophthalmological Clinical Institute of the Royal Prussian University of Berlin, etc. Translated and Edited by CHARLES A. OLIVER, A.M., M.D., one of the attending surgeons to the Wills Eye Hospital. Philadelphia: P. Blakiston's Son & Co. 1899.

THIS work is embodied in a volume of convenient size, comprising two hundred and seventy-four pages. The text is divided into a general and a special part. The "general" part is devoted to the consideration of massage, thermal agents, electricity, and general treatment. The "special" part is devoted to the consideration of the treatment of special diseases of the eye, taking them up in logical order. The context is largely a compilation of the published and unpublished views of European and English ophthalmic surgeons on ocular therapeutics, and reflects the views of the author to only a small extent. To the student and practitioner in ophthalmology the work is of much value, since many of the most important and useful formulæ and methods of treatment are here grouped in one volume and are easily accessible. The drug values are given in the metric system, and their equivalents in apothecary's weight and measures are added in each formula.

# Clinical Department.

## CARBOLIC-ACID POISONING.

By J. DRYSDALE BUCHANAN, M.D.,
NEW YORK.

On August 25th I was called to see a case of carbolic-acid poisoning. The patient, a woman of about thirty-five years of age, had swallowed over an ounce of ninety-five per cent. carbolic acid. Arriving on the ambulance of the Flower Hospital a short time after her swallowing of the acid, I immediately gave her a hypodermic of sulphate of sodium. Then, as no one at the place showed any disposition to help me to wash her stomach, I had her removed to the hospital. Here, with the aid of the house surgeon, Dr. J. W. Decker, I succeeded in washing the stomach with a thirty-five-per-cent. solution of alcohol, using about two quarts of the alcohol solution. The patient entirely recovered, although her face was badly burned with the acid, and the mucous membrane of the mouth seemed entirely destroyed.

I believe that this is the first time that alcohol has been used internally for the burns of carbolic acid.

## A CASE OF CRESCENT MALARIA OCCURRING IN A BOY AGED FIVE YEARS, ALWAYS RESIDENT IN NEW YORK.[1]

By HENRY HEIMAN, M.D.,
NEW YORK.

This specimen, which I exhibit to-night, which was derived from a patient whom I had the honor to present at a meeting of physicians, held at the residence of Dr. A. Jacobi on Friday, March 24, 1899, is of unusual interest, first, because it represents an unquestionable and undoubted case of crescent malaria, and second, because the patient, a boy aged five years, has always resided in New York City.

This case disproves the claim made by Osler in the New York Academy of Medicine about one year ago, that æstivo-autumnal malaria does not occur endemically north of Chesapeake Bay. Although Osler's experience has been confirmed by our New York hæmatologists, it would appear that the case I am about to describe is an exception to the rule. My patient, a boy five years old, born in the lower portion of the city, was, according to the statement of his parents, never outside of the city limits, and is at present residing on the east side uptown. The boy is his parents' third child; he was breast-fed, and his mother believes that he had an attack of malaria last October, as he had fever and convulsions. Inasmuch as the patient was not under my professional care at that time, I am unable to state whether the mother's view of the nature of the trouble was correct. His present illness dates back about four weeks, at which time he was brought to my clinic at the Mount Sinai Hospital dispensary. His temperature was 102° F. per rectum. The spleen was enlarged and was palpable up to two and one-half inches below the free border of the ribs. I made a peripheral blood examination and prepared three specimens, in one of which I found the typical crescent malarial organism. Two weeks after treatment began a second blood examination was made by me, at which time the child had no fever. Ten slides were examined, in one of which another typical crescent malarial organism was discovered. In New York City cases of the tertian type of malaria in children are not at all unfamiliar, while the crescent type in children is, as stated before, supposed to be solely brought here from southern climates. I believe this is the first clear case on record. The quinine was administered according to the following prescription:

| | |
|---|---|
| R Quininæ sulph | 2.0 |
| Acidi hydrochlor. dil | 1.5 |
| Syrup. simplicis | 30.0 |
| Aquam | ad 60.0 |

M. S. ʒi. every three hours.

I believe that the best results can be obtained by pursuing all types of malarial organisms with quinine, by administering it intermittently for a period of at least six months after the abatement of the usual symptoms. This I do on the principle that we allow the spores or segmenting bodies of the malarial organisms, which are believed to be not susceptible to the quinine treatment, to develop into mature malarial organisms, at which time they are susceptible to the action of quinine. The point of greatest interest in this case was the mode of infection. While it is a generally accepted theory that malarial infection is carried by mosquitoes or other insects, there is a strong possibility that the crescent malarial type can occur endemically in this city or vicinity. However, I am not unmindful of the fact that a great number of crescent malarial cases in this city last summer were directly imported by our soldiers.

## TREATMENT OF PULMONARY ŒDEMA OF CARDIO-NEUROTIC ORIGIN.

By D. J. HAMBURG, M.D.,
NEW YORK.

There was under my care during the months of July to October, 1898, a patient with a marked myocarditis and mitral lesion of several years' standing. This patient, a woman of about fifty years of age, was of a highly neurotic temperament, and it was due to this fact and the knowledge that she had a diseased heart, that she at times worked herself into a state of intense nervous excitement. At such times the heart soon became unequal to the strain upon it, and a profound disturbance of the circulation followed, causing a marked pulmonary œdema.

During the period of three months that the patient was under observation, she had four of these "attacks." They varied as to severity, but all were serious and any one might have terminated fatally. The patient was in a sitting posture in bed gasping for breath, and the ominous râles, terrified ashen-gray countenance, and the moist, cold body made a typical picture of fear, distress, and suffering.

Recently there came under my observation another patient with pulmonary œdema, and this case in origin, symptoms, and manner of response to treatment, was exactly the same as the one described. Both were patients with a chronic heart lesion and both were neurotics. The one marked feature of these two cases of pulmonary œdema, in contradistinction to those cases which we see as the terminal stage of acute diseases, was fright. Both patients were in imminent fear of death. On the contrary, patients with pulmonary œdema, after passing through the stages of an acute disease, often do not seem to suffer at all. They are apathetic, and it is the exception for them to realize their condition. The mental state then is seen to influence the condition so markedly that it must be considered in the treatment. It is essential to quiet the patients. For this purpose the first patient received morphine sulphate gr. $\frac{1}{8}$ every half-hour until one-half grain was given. Sometimes this would suf-

fice. If it did not, another dose or two would accomplish the purpose. The patient was also given cardiac stimulants at short intervals, and counter-irritants were applied to the chest, front and back. This treatment was uniformly successful.

In the second case an initial dose of morphine sulphate gr. $\frac{1}{4}$ was given. This relieved the patient so markedly in less than a half-hour that no more morphine was given, the stimulative treament alone being continued.

The happy issue in these cases would indicate that they represent a class in which morphine is not only indicated but is an important feature of the treatment. It neither embarrasses the respiration nor increases the congestion. It can be given fearlessly and be persevered in.

## Society Reports.

### ROCKY MOUNTAIN INTER-STATE MEDICAL ASSOCIATION.

*First Annual Meeting, Held at Salt Lake City, July 25 and 26, 1899.*

The Rocky Mountain Inter-State Medical Association, organized at Denver last year, held its first scientific meeting at Salt Lake City, July 25th and 26th. It started with a membership of one hundred, and an attendance of about sixty.

The president, Dr. Charles Pinckney Hough, of Salt Lake City, took the chair; and an address of welcome was delivered by the Hon. Heber M. Wells, governor of Utah.

**The Medico-Legal Supervision of Prostitution.**—Dr. Salathiel Ewing, of Salt Lake City, urged the dangers of syphilis and gonorrhœa, and their liability to affect the innocent. Since prostitution could not be eradicated it should be supervised, so as to lessen the ravages of these diseases. He favored licensing and rigid supervision. Funds obtained by the licensing of prostitutes could be rightly employed for the limitation of the diseases in question, and the support of reformatory institutions and hospitals. Weekly inspection should be practised; strict quarantine must be maintained, and those found diseased should receive hospital treatment. While he entertained the highest respect for the clergy, he thought that in regard to this matter they had generally been in the wrong.

Dr. H. S. Scott, of Salt Lake City, would have prostitutes confined to certain houses, and examined twice a week by specially trained examiners.

**Treatment of Chorea.**—Dr. S. D. Hopkins, of Denver, had been best satisfied with the results obtained by the administration of antipyrin in the manner first suggested by Eskridge. This was to give the drug in increasing doses, beginning with one grain for each year of the child's age, and increasing one grain each day. In the mildest cases the child was permitted to sit up a part of the day, and the antipyrin was given only in the evening. In severe cases absolute rest in bed was required and the dose of antipyrin was given three times a day. So soon as the choreic movements ceased or greatly diminished, the use of antipyrin was stopped, and Fowler's solution and iron were given until two or three weeks after the cure appeared to be complete. In giving large doses of antipyrin (gr. xx. three times a day to one child eight years old) certain precautions had to be observed. The child must be kept in bed and carefully watched. If there was heart disease or any fever, antipyrin should not be given. He had seen no bad results from its use; and in all the nineteen cases on which his paper was based rapid cures were obtained.

**Hydatid Mole.**—Dr. Solomon G. Kahn, of Leadville, reported a case of hydatidiform mole, or cystic degeneration of the chorion, from his own practice, with three other cases hitherto unpublished, from the practice of others. He had also sent letters of inquiry to four hundred physicians, from whom he received seventy-eight replies, reporting altogether twelve cases. This illustrated the rarity of the disease, and the impossibility of obtaining valuable statistics regarding it. The results of inquiries with regard to factors of causation had been quite negative.

**Hæmophilia.**—Dr. A. A. Kerr, of Salt Lake City, reported several cases of this condition. One was that of a boy, ten years of age, who was bleeding from an abrasion of the gum. A maternal uncle had died of hemorrhage following an operation. The parents were healthy, as were two of their children. Two other children had been bleeders, dying from hemorrhages at the ages of twelve days and six months respectively. The second case was that of a baby ten months old, whose family history was negative.

**The President's Address.**—Dr. Hough delivered his address at the opening of the afternoon session of the first day. In it he emphasized the need of closer association among the physicians of the inter-mountain States. They had many themes of especial interest in common, and were too far removed to attend the special society meetings held in the East. They could, however, meet each other once a year at some place in the inter-mountain region with great advantage. The orator was in favor of proper regulation of the practice of medicine, but thought that medical laws should be so modified as to permit a physician of established fitness to practise in any State without having to pass an examination which some of the examiners might have been able to pass when they first graduated. If membership in the American Medical Association was not a sufficient guarantee of fitness to practise anywhere, that association ought to be reorganized.

**Use of the Hæmatokrit.**—Dr. Judson Daland, of Philadelphia, urged the practical value of blood examinations with this instrument. He pointed out the great amount of time required to make a careful blood-count, the importance of duplicating it to obtain a reliable result, and the great probability of serious inaccuracy. The hæmatokrit did not exactly replace the blood-count, but the ease with which the volumetric estimate of the corpuscles could be made gave it greater clinical value. More time was required to keep the apparatus in order, and get it thoroughly cleaned, but with an assistant the volumetric estimate could be made in three minutes. A diluting fluid to prevent coagulation was not essential unless the tendency of the blood to coagulate was very great; but rapid manipulations were necessary to secure accurate results without it. He employed ten thousand revolutions of the tube per minute, for two minutes. This gave fifty per cent. as the volume of corpuscles in normal blood. By multiplying this volume by two we could easily obtain the percentage of corpuscles as compared with normal blood taken as one hundred per cent. For comparison with blood-counts the one hundred per cent. so obtained might be taken as representing five million corpuscles to the cubic millimetre.

**A Form of Fibroid Phthisis Caused by Quartz Dust.**—Dr. W. W. Betts, of Salt Lake City, called

attention to the terrible mortality of the lung trouble induced by the dust of the De La Mar mills, where certain gold-bearing ores were reduced to a fine powder, and the air was constantly filled with an impalpable dust. It was stated that all who had worked in these mills from seven to nine months previous to January, 1898, were now dead. The total deaths up to March 1st of the present year he believed to be one hundred and sixty-six. He reported in tabular form fourteen cases of the disease, occurring in men of from twenty to forty-three years of age, and previously healthy. One was able to work twenty-three months, and had lived two years afterward. Another had worked but three months, and died seven months later. The average time the men were able to continue working was thirteen months; and the average time they survived after leaving the mill was ten months. The trouble began with attacks of acute bronchitis, and inflammation of all the exposed mucous membranes. Later there were loss of appetite and loss of weight, rapid respiration, and general malaise. The pulse ranged from 90 to 120, and became weak and intermittent, and in the late stages the temperature rose to 102° or 104° F. Two autopsies showed great disease of the pericardium, the lung tissue excessively firm, with great increase of connective tissue, and the air-cells partly obliterated. On chemical analysis, the lung tissue was found to contain 2.8 per cent. of silica, and the bronchial glands 3.8 per cent. There was tellurium in the ore, but no arsenic. The only remedy was prophylaxis.

Dr. P. E. Jones, of Salt Lake City, thought the disease in question was the same as that which affected the employees in cutlery works and grindstone quarries, and to which grain-shovellers were especially liable. So long as life was less valuable than gold, the sacrifice would continue.

Dr. F. Clift, of St. George, Utah, said all the men who left St. George to work in that mill came back with this trouble. There were three of them still alive, but far on the way to follow their fellows. There was not the slightest doubt but that all who now worked in the mill were likewise doomed.

Dr. Mayo, who had been surgeon for the De La Mar Company for four years, had carefully investigated the subject with the aid of the company's records, and had found that only thirty-four had died who had been employed during that time. He believed a similar mortality would be discovered among the workers in other mills handling similar ores. When the disease was once contracted, it probably was necessarily fatal. Since the attention of the company had been called to the matter, extensive changes had been made in the mills. Fans, hoods, and ventilators had been put in, and respirators supplied for the men, with instructions about using them. Recently an inspector of the New York Life Insurance Company had reported that the workers in these mills were in no more danger than the workers in the flour mills of Minneapolis.

**Cases of Repeated Extra-Uterine Pregnancies.**—Dr. C. K. Fleming, of Denver, reported two cases. The first case, after marked evidence of a rupture of the sac, had presented the symptoms of sepsis, and the patient was treated three weeks for typhoid fever, before Dr. Fleming saw her. She promptly recovered after the evacuation of a pelvic abscess. After eighteen months of regular menstruation, she had the same train of symptoms. She refused operation, but slowly recovered without it. The second patient was operated on shortly after the occurrence of symptoms of tubal rupture, and a pelvic hæmatocele was found. One year later similar symptoms appeared, and on operation the right tube was found ruptured and containing a large blood clot. This patient also recovered. There was no history pointing to previous disease in either case.

**Carcinoma of the Uterus.**—Dr. W. W. Grant, of Denver, pointed out that the universal increase in the mortality from cancer made its causation and prevention of practical interest. The theory of a specific parasite seemed on the whole to be gaining ground. Certain it was that cancer occurred chiefly in parts most exposed to both traumatism and infection. On early diagnosis rests the only chance of cure. He favored frequent examinations of women near the menopause, and microscopic examinations of suspicious lesions. In women who had borne children, all lacerations of the cervix should be repaired at forty years of age.

**Treatment of Acute Conjunctivitis.**—Dr. Edward Jackson, of Denver, said that acute conjunctivitis included, beside the effects of eye-strain and local irritants, at least five specific infections, and that successful treatment depended on the careful discrimination between these different classes of cases. Eye-strain was always to be thought of and eliminated. In all forms of conjunctival infection, complete cleansing at sufficiently short intervals was of the greatest importance. Protargol was to be employed for purulent conjunctivitis, with applications of a strong solution of silver nitrate in bad cases. Mydriatics or cocaine should not be prescribed for acute conjunctivitis, because they were more likely to do harm than good. To secure the greatest cleanliness of the conjunctiva, and to limit the dangers of infection, all forms of poultice, bandage, and compress should be carefully avoided.

**The Eyes and the Brain.**—Dr. R. F. Le Mond, of Denver, spoke of the important relations between eye lesions and brain disease. He believed the pathological changes often found in the astigmatic eye were for the purpose of relieving the strain that would otherwise come upon the brain.

**Improved Forms of Artificial Eyes.**—Dr. G. Melville Black, of Denver, in a paper on ocular prothesis, called attention to the recent suggestion of Snellen, of different forms for artificial eyes. The shell heretofore generally used was designed to be worn over a shrunken eyeball, and not to fill up the orbit after an enucleation. There were also needed a concavo-convex form of artificial eye, to be worn over a small stump; and a double convex form, to occupy the orbit properly after enucleation. Artificial eyes of these latter forms not being obtainable yet in this country, he had resorted to the expedient of filling in the cavity of the ordinary shell with a preparation of wax (Gilbert's temporary stopping) used by dentists. This had proven quite satisfactory in preventing the unsightly sinking of the artificial eye, and the accumulation of discharges behind it and irritation of the conjunctiva by the formation of a vacuum beneath the shell.

**Operation for Gall Stones.**—Dr. I. B. Perkins, of Denver, reported three cases of distention, inflammation, and sepsis of the gall bladder, arising from obstruction of the ducts by gall stones, and in which a cure resulted from removal of the stones, and drainage. Gall stones were so common, and gave rise to so many and such obscure symptoms, that the subject was one of great practical importance. The greater frequency of gall stones among women (more than two to one) was probably due to constriction of the abdomen by customary styles of dress and to a more sedentary life. He had done the operation of incision, removal of the contents of the gall bladder, and drainage, with closure of the opening subsequently. He believed the operation of immediate closure of the gall bladder, and dropping it back into the abdomen, was rarely applicable to cases really requiring opera-

tion, and that it ought not to be called the "ideal" operation. Of the stitches passing through the abdominal wall to close the incision, those opposite the opening into the gall bladder were made to enter its wall, and then emerge from it again, like a Lembert suture, before crossing the incision. Two or three of these stitches at the centre of the incision were left untied, and the gaping wound was packed with gauze to insure free drainage. When drainage was no longer needed, the edges of the abdominal wound were slightly freshened and the stitches tied, without the need of anæsthesia to introduce the sutures. The inversion of the edges of the incision in the gall bladder by stitches that acted upon it as a Lembert suture secured prompt union.

Dr. John B. Roberts, of Philadelphia, was favorably impressed with Dr. Perkins' plan of closing the wound. When a gall stone, however, was impacted in the common duct it would be extremely difficult to dislodge it by any such operation. He suggested that the duct might be followed down to its entrance in the duodenum; and an opening made in the duodenum opposite this point. A probe could then be introduced through the mouth of the duct, and the obstructing stone pushed back into the gall bladder and removed. The dilatation of the duct above the point of obstruction would commonly render the dislodgment of the obstruction in this way not difficult.

**Appendicitis with Anomalous Position of the Appendix.**—Dr. A. J. Hosmer, of Salt Lake City, exhibited a boy operated on for appendicitis, in whom, through the usual incision in the right iliac region, no trace of the appendix or head of the colon could be found. A mass of exudate could, however, be felt far up and to the left. A median incision was made and the gangrenous appendix removed from the midst of this mass. In this case the pain was referred to the left side.

**Suprarenal Extract in Surgery of the Ear, Nose, and Throat.**—Dr. W. W. Bulette, of Pueblo, reported upon an experience with this agent in two hundred and one cases, one hundred and thirty-seven of nasal, forty-six of throat, and eighteen of ear disease. It produced anæmia of the tissues, reducing swelling, and preventing hemorrhage that would otherwise be very troublesome by obscuring the field of operation. It also aided in prolonging local anæsthesia, which was often cut short by the hemorrhage washing away the cocaine. With its help, operations could be done without pain or loss of blood; there were no unpleasant effects, and there was little secondary hemorrhage. Since employing it, cases presenting symptoms of cocaine poisoning had been fewer. It reduced to a minimum the patient's dread of operation.

**The Bottini Operation for Hypertrophy of the Prostate.**—Dr. Leonard Freeman, of Denver, reported eight cases of enlarged prostate operated on with the Bottini instrument, which burned grooves in the hypertrophied organ. The instrument consisted of a platinum galvano-cautery knife, arranged like the male blade of a lithotrite. Any general burning of tissue in contact with the instrument was prevented by a stream of ice-water circulating through it. The operation caused little after-pain or bleeding. Of the eight cases, five were practically cured. One patient improved at first, and still had no residual urine, but again suffered from pain and frequent urination as badly as ever, and cancer was now suspected. He believed this the best operation yet proposed for enlarged prostate. Few men submitted cheerfully to castration or vasectomy. Bottini's operation caused no external wound. It could usually be done under local anæsthesia. In the above cases general anæsthesia was used but once. The burned surfaces were practically sealed against absorption. The benefit was immediate. There were few relapses. The patient could move about within a day or two. The mortality of the operation was less than by other modes of operation. The patient would submit to this operation when he would not submit to any other.

**Disease of the Mastoid.**—Dr. C. K. Cole, of Helena, Montana, reported four cases, illustrative of sixteen that he had seen in the last twenty months. Such cases were essentially surgical. He advocated thorough opening of the mastoid and irrigation with not less than two to four quarts of hot sterilized water or antiseptic solution. The periosteal incision might sometimes be useful in young patients. In extreme cases multiple openings were advised.

Dr. H. R. Bull, of Grand Junction, had recently encountered two cases of mastoid disease following measles. He employed hydrogen dioxide as a cleansing agent in these cases.

**Some Toxic Causes of Insanity.**—Dr. Hubert Work, of Pueblo, called attention to the generation within the body of poisons capable of causing mental alienation. Loss of weight and anorexia occurred so constantly in connection with certain psychoses as to suggest at least a common cause. Some of the most distressing symptoms of dyspepsia were mental. It was certain that insanities did result from prolonged digestive disturbances. Auto-infection from the alimentary canal might alone cause many cases. He reported four illustrative cases, in which treatment directed to the source of the toxic influence brought about a cure of the mental symptoms. The first, a case of digestive disturbances, was cured in three months. The second, a case of rheumatism, was cured in eighteen months. The third was a case of chronic cystitis, which was cured in four months. The fourth, due to hepatic derangement, was cured in two months. Insanity was a symptom, and removal of its cause brought recovery. In no disease was proper medical treatment more needed at the beginning.

**Auto-Intoxication and Blood Morphology in Relation to Operations.**—Dr. P. S. Keogh, of Salt Lake City, discussed the bearing of these conditions on the preparation of a patient for an important surgical operation. The older surgeons well knew that complications followed less frequently when the patient had been prepared for operation by catharsis. Symptoms of indigestion and gastro-intestinal disease should always be carefully looked for. Examination of the urine might reveal a deficient elimination of solids. General anæsthetics increased the danger from auto-intoxication. The examination of the blood, particularly with reference to the percentage of the oxyhæmoglobin and the condition of leucocytosis, gave very important evidence regarding the patient's power of resistance.

**Cases of Infection by the Bacterium Coli.**—Dr. J. N. Hall, of Denver, stated that this organism, at first regarded as only a harmless inhabitant of the alimentary canal, was now known to be one of the most important pathogenic bacteria. Probably the name was now applied to a whole group of bacteria, presenting varying degrees of virulence, and not to a single species. He reported two fatal cases, both patients being men. The first patient, after twenty-four hours' retention of urine, presented in it great numbers of colon bacilli. Then ensued pleuritis, broncho-pneumonia, pericarditis, a purpuric eruption, pyelitis, and perinephritic inflammation. In the second patient there was a purpuric eruption, and abscesses were scattered over the body. The bladder was distended with acid, foul-smelling urine, containing sugar and loaded with bacilli, and gas was generated within the bladder. The spleen and liver were

found to be septic. There were nephritis and a large abscess behind the sternum.

**The Early Diagnosis of Tuberculosis.**—Dr. A. M. Holmes, of Denver, thought there were recognizable early evidences of this disease; and if these were heeded recovery might be brought about. Loss of appetite and weight, gastric disturbances, dyspnœa, and persistent cough should lead to repeated examinations. The importance of the early examination of the sputum, he thought, had been overrated. If the bacilli were found, the evidence would be conclusive. But they might exist, in concealed foci of infection, a long time before making their way into the sputum. He regarded subnormal morning temperature and "cog-wheel respiration" as important symptoms, but hemorrhage was not. Early in the disease the study of the blood was more important than the study of the sputum, especially the examination of stained blood-films with a differential count. There was no excuse for delay in the diagnosis of tuberculosis, for we had a certain test in the reaction produced by tuberculin. He employed at first an injection of 1 mgm. If no reaction followed this, three days later 3 mgm. were injected; and if this produced no effect, 5 mgm. were tried. The injection was made in the evening, and the reaction commonly occurred six to twelve hours later.

**Officers for the Ensuing Year.**—The following were elected: *President*, Charles K. Cole, of Helena, Mont.; *Vice-Presidents*, Leonard Freeman, of Denver, and R. H. Reed, of Wyoming; *Treasurer*, Charles G. Plummer, of Salt Lake City; *Recording Secretary*, Donald Campbell, of Butte, Mont.; *Corresponding Secretary*, S. D. Hopkins, of Denver.

Dr. Judson Daland and John B. Roberts, of Philadelphia, were elected honorary members. The place selected for the next meeting is Butte, Mont., and the time the last week of August, 1900.

## NEW YORK COUNTY MEDICAL ASSOCIATION.

*Stated Meeting, June 19, 1899.*

Frederick Holme Wiggin, M.D., President.

**Acute Bronchitis—A Symptom; Its Treatment from an Etiological Standpoint.**—Dr. Thomas F. Reilly read a paper with this title (see page 218).

**A Fœtal Specimen.**—Dr. L. W. Zwisohn presented a complete ovum—the fœtus enclosed in its membranes. He had been called to see a woman about thirty-six years of age, who thought she was pregnant about four weeks. Digital examination had revealed a patulous os, and the ovum just about to be discharged. It was apparently a fœtus at about the sixth week of gestation. The toes and fingers were just beginning to develop. The specimen had been well preserved in fifty-per-cent. alcohol.

**Non-Malignant Strictures of the Œsophagus, and Their Treatment.**—Dr. Henry Mann Silver read this paper. The author reviewed the literature for the past ten years, and reported a case of non-malignant stricture occurring in his own practice. This case was that of a child of four years, who about one year previously had drunk some Javelle water. Although medical advice had been promptly sought, the fauces and œsophagus had been severely inflamed. No attempt had been made to keep the œsophagus open before the child came to the hospital on October 5, 1898, and the quantity of food that could be swallowed had steadily diminished. A No. 11 bougie had passed down a distance of nine and three-quarters inches from the dental arch before meeting with any obstruction, and about the same result had been observed under anæsthesia. As the child received very little nourishment, surgical interference was demanded, and accordingly gastrostomy had been performed. The child stood the operation well, and the operation wound had healed by first intention. The operation had been done on October 17th, and just one month later the first effort had been made to perform retrograde dilatation. The electric head-light had been found a very valuable aid in the treatment, as had also the use of specially made endoscopes constructed somewhat after the manner of Kelly's cystoscopes. About the middle of January of the present year dilatation by way of the mouth had been first attempted, and a No. 9 bougie had been passed. It had been noticed early in April that after a rest of two weeks the instrument introduced by the mouth passed the stricture much more easily than before. The gastric fistula had been closed on April 18th, or six months after the gastrostomy. On May 7th the child had been discharged from the hospital and made an out-patient. An interesting feature of this case was the ease with which the course of the bougie could be traced from the mouth to the strictured point by the aid of the fluoroscope. Another interesting feature was the subnormal temperature in the morning, reaching at times as low as 96° F., and continuing throughout the entire course of treatment. This subnormal temperature should warn us to guard carefully against exposure and exertion in the morning. During the time of active treatment there had been no leakage, and at no time had there been any redness of the skin.

Treatment: The speaker then took up systematically the consideration of the modern treatment of such cases. He said that the point of stricture could be easily located by means of the *x*-rays and the passage of a metallic bougie by the way of the mouth. The ordinary bulbous bougie would answer nearly as well. The great difficulty in the treatment of these cases was not that the stricture was absolutely impassable, but that in most cases it was impossible to cause the tip of the instrument, however small, to engage in the opening in order to carry on the dilatation. The great question to decide was whether a temporary opening in the stomach—a gastrotomy—or one to remain open a longer time—a gastrostomy—should be made. When a powerful corrosive had been swallowed, followed by severe inflammation and evidence of rapid stricture formation, or when the regurgitation of a quantity of food at one time showed that a considerable pouch had formed, it seemed to him that a gastrostomy was advisable; but when the inflammation had been moderate, and the regurgitation of fluid was quite small and occurred almost as soon as swallowed, a gastrotomy appeared to him preferable. In the future he would fear pouching of the lower œsophagus more than a tight stricture situated in the same location. Before performing a gastrotomy, that position for the incision should be selected which would give the freest access to the cardia, and which would allow of the conversion of a gastrotomy into a gastrostomy if necessary. The old operations of Fenger and others were not to be thought of at the present day. In one of the modern operations the fistula passed in a curved direction through the abdominal parietes, and underneath the stretched cutaneous "bridge." Retrograde dilatation had been found perfectly feasible through such a fistula, but the operation was not well suited for cases in which the stomach was greatly contractured. The interior of the stomach should always be examined before deciding whether the operation should be completed as a gas-

trotomy or a gastrostomy. This procedure could be facilitated by the use of silk sutures so inserted as to give the operator control over the stomach. In practising retrograde dilatation almost invaluable assistance would be rendered by a thread in the œsophagus and stomach. It had been suggested as an easy method of introducing the thread to attach it to a shot or make a small knot in the end of it and allow the patient to swallow it slowly. Dr. Abbe had combined the method of dividing the stricture from below with the use of bougies, and then divided the stricture not with a knife but with a string. Having succeeded in cutting through the stricture thoroughly, and passing bougies of fair size by the mouth, the wounds should be closed at once. The after-treatment consisted in the passage of the largest-sized bougies possible at least once a week at first, and later at longer intervals. The patient should be encouraged to eat solid food in order to assist in keeping the œsophagus open. Among the thirty-eight recorded cases, there had been no deaths due to the immediate effects of this method of treatment. This remarkable record should lead to early surgical interference—as soon as the scales showed a steady decrease in body weight. If the gastrostomy was deferred until the patient had reached a condition of advanced inanition, the operation became a wellnigh hopeless one instead of a procedure attended with little risk and capable of saving life in a very large proportion of cases. When the operation was long postponed the patient was apt to starve with a full stomach and a full intestine.

**The Most Suitable Instruments.**—Dr. George Woolsey opened the discussion on this paper by speaking of the instruments most suitable for retrograde dilatation, and their mode of introduction. It was conceded by all, he said, that the easiest method of introducing the instrument through a strictured œsophagus was from below, because of the presence of pouches and the frequently eccentric position of the stricture. In general, it might be said that if the stricture was passable from below, one could generally succeed in forcing through a bougie of fair size. Having once succeeded in doing this, the surgeon should attach one or more strings to the bougie, and draw them out of the mouth. Considerable difficulty was experienced in some instances in entering the lower end of the œsophagus, and often for the reason that it was not in the position described in the anatomical text-books. By pulling down on the lesser curvature of the stomach and allowing the bougie to follow this curvature, it would pass into the lower end of the œsophagus. This was the best procedure for accomplishing this with which he was acquainted. When the stricture was fairly narrow, and rather long, a useful instrument was a small, tapering bougie having a thread attached to its tip. In his opinion, internal œsophagotomy, either from below or above, should be condemned. The string-saw method described in the paper was a most useful one.

**Gastrotomy and Gastrostomy, with Dilatation of the Lower Third of the Œsophagus.**—Dr. Willy Meyer was invited to discuss this part of the subject. He said that strictures of the lower third were usually very dense, and although the result in such a case with a string-saw was good at the time of the operation, it would often be found after a few days that another operation was demanded. The requirements of the operation were: (1) The original incision must be used in connection with establishing the fistula; (2) the fistula must be watertight, and (3) it must close spontaneously after removal of the tube. He advised pulling out the stomach and making the incision in it horizontal. For strictures of the lower third Dr. Abbe's method should be tried. If any difficulty was experienced in passing the larger bougies, especially from above downward, a gastric fistula should always be established. Dr. Meyer exhibited two adult patients upon whom he had operated by Kahler's method, in order to show that the fistula was thoroughly watertight.

**External Œsophagotomy for Strictures Low Down.**—Dr. Joseph D. Bryant discussed this topic. He said that the performance of external œsophagotomy in one having a short, stout neck was not to be lightly regarded by any person. By a low œsophagotomy the distance to the cardia was lessened, and the route was more direct than in the other method. The speaker described a modification of the string-saw method which he thought might be applied by way of the mouth, thus eliminating certain dangers and supplementary features by the single string method. In performing external œsophagotomy great care should be exercised in opening the œsophagus. The latter should be opened as far posteriorly as possible in order to avoid injuring the recurrent laryngeal nerve.

**Division of Low Œsophageal Strictures.**—Dr. Robert Abbe discussed this topic. He said that it was impossible to penetrate many of these tight strictures from above, and hence the great advantage of dilating and cutting them by a comparatively safe method. The one which he had devised, and which had been already alluded to this evening, had been first employed seven years ago upon a lady whose œsophagus had become strictured as a result of swallowing caustic potash. She had become greatly emaciated, and was in wretched condition at the time the treatment had been undertaken. In that case he had found that two or three small bougies could be passed through from the stomach to the mouth. To facilitate the passage of the larger ones he had passed a piece of heavy braided silk as a guide. Finding one of the bougies hugged tightly at this time, he had discovered that by pulling the silk to and fro he could rapidly enlarge the strictures so as to admit of the successive passage of several much larger bougies. He had seen this lady very recently, and she was in perfect health. The largest size of œsophageal bougie she passed upon herself once or twice a year merely as a precautionary measure. The speaker said that the very ingenious arrangement devised by Dr. Bryant seemed to him a very excellent substitute, but the possibility of using it from above did not appeal to him as of much importance. The use of cutting instruments, such as the œsophagotome, seemed to him decidedly dangerous at all times. In exploring the stomach with the finger passed through the gastrostomy wound, he had been impressed with the fact that at first the stomach appeared as a smooth dome without even a dimple to represent the œsophagus, but after pressing for a moment the sphincter muscle would yield and a dimple would be formed, indicating the position of the lower opening of the œsophagus. He had recently made an interesting application of the string-saw method in a case of laryngeal stenosis, the string being passed up through the tracheotomy wound.

**Rest of the Part Exceedingly Beneficial.**—Dr. John A. Wyeth said that early operation in all these cases, whether the stricture was the result of irritation by an escharotic or of malignant disease, was indicated, because in both classes of cases rest of the part was exceedingly important. A case was cited in which a woman, who was about five months pregnant, had swallowed a quantity of lye. He had at once performed gastrostomy, and had insisted upon complete rest of the œsophagus. She had gone on to full term, and had been delivered of a healthy child, and a few months later the inflammatory condition of the

œsophagus had subsided completely without a bougie having ever been passed.

**Œsophagoscope.**—Dr. Max Einhorn said that in many cases the œsophagoscope made it possible to see the point of stricture or the location of the bougie. It would be found useful in some cases in which the endoscope did not work well. Reference was made to two cases of benign stricture of the œsophagus, one at the upper and the other at the lower part of the œsophagus, in which dilatation had succeeded admirably. He also spoke of a class of cases that might be called spurious strictures, as careful investigation showed that there was no organic stricture, but rather a spasmodic condition. He agreed with the reader of the paper that gastrostomy should be performed early, if dilatation by means of bougies introduced through the mouth had failed.

Dr. B. Farquhar Curtis was invited to summarize the subject. He said that it was evident that there was some hope for all these cases of œsophageal stricture, even when dilatation had failed. However, all the stumbling-blocks had not yet been removed. It was not easy to cure an œsophageal stricture even by performing external œsophagotomy and gastrostomy, and using the string-saw method. This was certainly the safest method, but even it was not entirely free from danger. There was a possibility of infecting the wound, or of passing into the pleura. The beauty of the method was that by keeping the fistula open and the strings in place it could be employed again and again over a period of many weeks, the patient's strength being kept up by feeding from below. In one of his cases gastrostomy alone had been sufficient to effect a very considerable dilatation of the œsophageal stricture. He had found some difficulty in keeping the string in place and preventing it from cutting the lip, but he had finally obviated this completely by tying together the ends of the string protruding from the mouth and fistula. About once in twenty-four hours, through the efforts at swallowing this would make one complete rotation. The great trouble in most of these cases was recurrence of the stricture. These strictures should be treated on the same principles as strictures of the urethra.

## THE NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, May 10, 1899.*

T. Mitchell Prudden, M.D., President.

**Report of the Committee on Microscopy on the Case of Mike Kelly.**—Dr. Harlow Brooks presented the report. He stated that the committee had subjected to microscopical examination the tumors from the scalp and the larger tumors of the skin of other regions in the well-known case of Mike Kelly, of Bellevue Hospital. These growths had all shown substantially the same characteristics, viz., that of a highly cellular fibroma, somewhat resembling fibro-sarcoma, but having a blood supply which was hardly sufficient for a tumor of the latter class. In the small nodules from the small intestine the pigment had been found lying between the peritoneal and muscular coats, and not at all within the cells of the tumor growth proper. These tumors had been slightly different in some respects from those on the external surface of the body, but essentially the same in structure. They contained a good deal of involuntary muscle, apparently derived from the coats of the intestine. These growths were made up of connective tissue containing a very large number of connective-tissue cells, some of these cells being apparently proliferating. He had not found any evidence of neuroma or of connection with nerve fibres. Sections of the tumor tissue were exhibited under the microscope.

**A Case of Asexualism.**—Dr. Brooks reported this case. (See page 221.)

**Report of Five Cases of Sudden Death Following Lodgment of Foreign Bodies in the Larynx.**—Dr. Leon T. Le Wald presented specimens from these cases. They had all occurred in males in middle or advanced life, and the foreign body had been in each case a piece of meat that had lodged in the pharynx just over the entrance to the larynx.

Dr. J. H. Larkin said that about two years ago he had seen a man who, while eating soup, had swallowed a piece of meat-bone measuring about half an inch in diameter. It had lodged in the ventricle of the larynx. About three days later he had entered the hospital much cyanosed and had died one hour later. At the autopsy the bone had been discovered and around it a good deal of ulceration. The cause of death had been œdema of the glottis.

Dr. Northrup remarked that he could recall a specimen presented some years ago to the society by Dr. Herman M. Biggs. It had been taken from a man who had dropped dead instantaneously while eating, and without having any convulsions.

**Tuberculous Myocarditis.**—Dr. F. C. Wood presented a specimen of tuberculous myocarditis removed from a child of nine months, at St. Luke's Hospital. At the autopsy no miliary tuberculosis had been discovered. There had been found firm white patches in the myocardium and on the surface of the ventricle. Only twenty-five or thirty cases of this form of tuberculosis had been reported, although it was common enough in connection with miliary tuberculosis. The case would be reported in detail later.

**Two Cases of Aortic Aneurism with Rupture into the Pulmonary Artery.**—Dr. Lewis A. Conner reported these cases, and presented the specimens. Both patients had come recently into the Hudson Street Hospital, and had died shortly after admission, so that the clinical records were incomplete. The first one, a man sixty-six years of age, a porter by occupation, had been admitted on April 10th with feeble heart action and deep cyanosis, but with no subjective symptoms except weakness. He said that he had felt well up to three hours before, when he had begun to feel drowsy. He was almost pulseless, but was free from dyspnœa. Auscultation over the precordium had revealed nothing but the extreme feebleness of the heart sounds. The heart was much enlarged, and both ventricles were found at autopsy much dilated, and their walls moderately hypertrophied. The heart muscle showed slight fatty and granular degeneration. The valves were normal in appearance and seemed to be competent. The aorta from its origin to a point beyond the origin of the innominate artery was the seat of dilatation and many atheromatous areas. At a point 3 cm. above the aortic valve was a recent tear, 2 cm. long, opening into the left pulmonary artery. The lungs were much congested and somewhat œdematous.

The second case was that of a man of forty years, a Danish laborer, who had been admitted on February 10th with a history of having been well up to twelve hours previously. Since that time he had been coughing up blood-stained sputum. While walking from the ambulance to the ward the pulse became weak, and he coughed up blood and serous fluid. He died in twenty minutes. At the autopsy the heart had been found considerably enlarged, and the left ventricle much dilated, but its wall was of normal thickness. The wall of the right ventricle was greatly thickened. From the right sinus of Valsalva, immediately to the right of the orifice of the right coronary artery, was an

aneurismal pouch the size of a walnut. It was filled with old clot, and seriously obstructed the flow of blood into the pulmonary artery. The aneurism had ruptured immediately behind the pulmonary valve. There was a clot extending into the pulmonary artery and almost occluding the right branch. The left lung was evidently œdematous, and the bronchi were filled with reddish fluid. In the upper part of the left upper lobe was an area of recent tuberculous consolidation, and there were evidences of an old tuberculosis. The aorta showed throughout considerable arterial sclerosis. The symptoms in these two cases presented a remarkable contrast, which it was not easy to explain by the pathological findings. In the first case it seemed as though the force of the current of blood in passing from the aneurism into the pulmonary artery must have been diminished; in the second case, the direction of the blood stream must have been upward into the pulmonary artery. He could not believe that the clot in the pulmonary artery had been there more than a very short time before death. Another interesting feature in the second case was the recent development of tuberculosis in a man of good physique. The association of this with a serious interference with the flow of blood into the lungs was exceedingly significant. Regarding the symptoms of rupture of aneurisms into the pulmonary artery the speaker said that in nineteen reported cases there had been either a systolic bruit, a continuous murmur, or a double murmur corresponding to both systole and diastole. There had been, in addition, the usual signs and symptoms of disturbance of the general circulation.

Dr. Mary Putnam-Jacobi suggested that the absence of the dyspnœa in one of the cases indicated that with the extreme cyanosis there had been more or less insensibility, and hence the lack of appreciation of the distress.

Dr. Northrup said, regarding the narrowing of the pulmonary artery and its relation to the development of tuberculosis, that he could recall six cases of congenital malformation in children, and one adult, in which there had been tuberculosis. It was well to remember that certain German surgeons claimed to treat tuberculosis of joints successfully by producing local cyanosis. He did not think the opinion was now so generally held as formerly that tuberculosis was associated with a small pulmonary artery.

Dr. Wood said that the surgeons attempted to produce local congestion in joint disease, and not a diminished blood supply, hoping thereby to control the tuberculous process.

**A Case of Canalized Thrombus of the Iliac Artery.**—Dr. George P. Biggs presented this specimen. It had been removed from a woman, thirty-seven years of age, who had died as a result of mitral stenosis. The only history obtained was that she had suffered from chronic valvular disease of the heart. The left common iliac artery was smaller than normal and very firm, as though filled with an organized thrombus. Transverse section of this thrombus showed ten longitudinal canals, each one-half to one millimetre in diameter, by means of which the circulation had been partially restored. The canals were chiefly in the periphery of the clot, and were found, on microscopical examination, to have an endothelial lining. The thrombus began 2 cm. from the aorta, and was 4.5 cm. in length, covering the opening of the internal iliac, and extending into the external iliac artery. No attempt had been made to follow the course of the collateral circulation, but it had been noted that the iliac vessels of the opposite side were unusually large.

**A Pin in the Vermiform Appendix.**—Dr. H. Brooks presented this specimen, which had been taken from a child of five years. The illness had begun six weeks before death with convulsions, followed by pain in the right ear, stiffness of the neck, dilatation of the pupils, vomiting, restlessness, and slight fever. When admitted to the New York Hospital there had also been noted internal strabismus of the right eye. The patient had developed delirium, giving place to stupor several days before death. The temperature had been between 99° and 100° F. during the last two weeks of life, and the highest recorded was 101° F. There had been no abdominal symptoms. The mother stated that eighteen months before death the child had swallowed a pin, which had never been found in the fæces. At the autopsy the dura mater had been tense, and the convolutions flattened. The dura was adherent to the right parietal lobe, and beneath the adhesions was a large single abscess, measuring 6.5 cm. vertically, 6.5 cm. antero-postriorly, and 4 cm. transversely. The contents of the abscess consisted of 200 c.c. of thick, yellowish, offensive-smelling pus. The abscess occupied all the right parietal lobe except the ascending parietal convolution, and the parietal portion of the convolution of the longitudinal fissure. There was destruction also of the posterior portion of the temporo-sphenoidal lobe. A fairly firm wall to the abscess had suggested that it might have existed for some time. Rupture into the subdural space was prevented only by the adhesions to the dura. The cerebral sinuses and both ears appeared normal. The vermiform appendix hung free in the peritoneal cavity, and measured 8 by 0.75 cm. There were adhesions of the omentum to the distal third of the appendix opposite its mesenteric attachment. Slight traction on the omentum had caused a partial breaking of the adhesions, and had exposed an opening, 2 mm. in diameter, in the anterior wall of the appendix, 2.5 cm. from the tip. Through this opening had projected the head of an ordinary pin, 2.5 cm. in length, covered with rough concretions. The point of the pin, which was toward the cæcum, was also embedded in the anterior wall of the appendix, nearly causing a second perforation.

Dr. Brooks said that he had reported some months ago a case of pin in the appendix. In that instance the head of the pin had perforated and formed a small localized abscess. There had been no symptoms referable to the appendix. He had learned that a series of thirty-three cases of this kind had been collected at the Johns Hopkins Hospital; that in the greater number of them the head of the pin had been found in the distal end of the appendix, and often there had been few direct symptoms referable to the appendix during life.

**Fish Bone in the Œsophagus.**—Dr. W. P. Northrup exhibited a sharp triangular piece of fish bone, having a sharp spur coming off from its base. He had removed it with the aid of a laryngeal forceps after having first located it with his finger.

**A Case of Meningitis.**—Dr. F. C. Wood reported a case of meningitis in which the upper surface of the hemispheres had been covered with a thick layer of pus. The patient had been in the hospital for some weeks with a pneumonia of the left lower lobe. It was supposed that resolution had taken place, but the symptoms had suddenly become worse; then meningeal symptoms had supervened, and death had occurred shortly afterward. At the autopsy there had been a well-marked œdema and congestion of the left lower lobe, but no consolidation. The spleen had contained infarcts. In the heart was a small clot situated underneath one of the valves and attached to the myocardium. Cultures made from the blood during life had proved negative, but the pneumococcus had been obtained in smears made from the contents of the abscess.

**Biliary Cirrhosis.**—The second specimen presented by Dr. Wood had been taken from a well-nour-

ished man who had been admitted in coma, with a subnormal temperature, and without any definite history. At the autopsy extreme jaundice had been noted, but no ascites. A number of small hemorrhages were found underneath the pericardium, and the stomach and duodenum contained a great deal of blood. The gall bladder was represented by a small mass of fibrous tissue without a lumen. In the common duct was a small oval transparent stone composed entirely of cholesterin. The surface of the left lobe of the liver was covered with small nodules. The case was evidently one of biliary cirrhosis. Microscopical examination of the liver had shown a thickening of the bile ducts and necrotic areas apparently the result of an old infection. There was also a diffused intralobular cirrhosis. Some of the cells of the liver had been well preserved. The spleen was small.

Dr. Brooks said that the first case recalled one that he had seen at the Harlem Hospital. There had been complete consolidation of the lower lobe of the lung at the time of admission. After about two weeks he had developed a meningitis, apparently of the cerebro-spinal type, and had died. The autopsy had shown a resolving pneumonia on the left side and a thick greenish exudate over the convexity of the brain, extending down over the cord. Smears from the lung had exhibited only the diplococcus of Weichselbaum. He had not been able by cultures to find the pneumococcus in the lung, but it had been present in the trachea and bronchi. In the cerebral exudate the pneumococci and Weichselbaum diplococci had been demonstrated. It was thought that the source of the trouble had been an infection of a bronchus with the Weichselbaum diplococcus, and that eventually it had been a case of mixed infection.

**Malignant Endocarditis — Infarcts in Lung, Spleen, and Kidneys.**—Dr. L. A. Conner referred to a case of malignant endocarditis which had resulted in death at the New York Hospital not long ago, with a very obscure history. A very large thrombus had been found filling up the whole tricuspid orifice. There had been not only many infarcts in the lungs, but one in the spleen and one in the left kidney as well. There had been nothing abnormal in the left side of the heart, and consequently he had been surprised at these findings.

Dr. Northrup remarked that in his experience the lesion had several times been in the right heart, and yet infarcts had been present in the spleen, lungs, and kidneys. It was his impression that this occurred frequently in primary ulcerative endocarditis.

**Osteosarcoma of Knee Simulating Tuberculous Joint Disease.**—Dr. Reginald H. Sayre presented a tumor removed from a girl of thirteen years. According to the history she had fallen last November, and struck the knee several times within a month. During the previous summer she had complained a little of pain in the knee. When first seen by him in the latter part of February, there had been some swelling of the upper part of the knee not unlike malignant disease. He had treated the case tentatively for a short time, thinking it possible that the disease was tuberculosis. Within a few weeks the bone had increased rapidly in size, and on exploratory operation a large bleeding tumor had been found. He had then amputated at the hip joint. Microscopical examination had shown the tumor to be a large spindle-cell sarcoma. The child had improved rapidly after the amputation, and had been discharged within two weeks.

In this connection Dr. Sayre exhibited a skiagraph of a round-cell sarcoma of the tibia that he had presented to this society about one year ago; also a skiagraph of a case in which there had been doubt as to whether the diseased condition of the fibula had been syphilitic or malignant. The skiagraph had proved disappointing as a means of differentiating between syphilitic and malignant disease of bone.

Dr. James Ewing remarked that skiagraphy should be of service in differentiating between round-cell and spindle-cell sarcoma of bone, for in the former the shaft of the bone was usually destroyed very early.

## Therapeutic Hints.

**Gastralgia.**—

℞ Chloral ..... gr. iij.
Sodii hyposulphat. ..... gr. vi.
Aquæ menth. pip. ..... ʒ i.
M. S. At dose. Repeat as required by frequency of attacks, guarding against over-use of chloral.

—*Riforma Medica.*

**Rheumatism.**—Apply locally:

℞ Phenacetin ..... ʒ i.+gr. xv.
Lanolin. ..... ʒ v.
Ol. oliv. ..... q.s.
M. ft. ung.

Or:

℞ Phenacetin ..... ʒ i.+gr. xv.
Spt. vini rectif.,
Aq. calid ..... āā ʒ iij.
M. S. Soak compresses in above and apply.

—*Rev. de Cienc. Med. de Barcelona.*

**Improved Lotio Alba for acne, etc.**

℞ Potass. sulphidi,
Zinci sulphatis ..... āā ʒ i.
Aquæ destillat.,
Aquæ camphoræ ..... āā ʒ i.
Aquæ rosæ ..... ʒ ij.
M. S. Shake and apply.

—Sherwell.

**Scabies.**—

℞ Sulphur. loti ..... ʒ i.
S Apply in the dry state to the whole surface twice a day and sprinkle a teaspoonful between the sheets at night.

—Sherwell.

**In Congestion of the Female Genital Organs.**—

℞ Magnesii sulph ..... 45
Ferri sulph.,
Manganes. sulph. ..... āā 10
Acidi sulphur. dil. ..... 4
Aquæ destill ..... ad 200
M. S. One tablespoonful in a wineglassful of water before meals.

**To Stimulate Diaphoresis.**—

℞ Camphoræ pulv ..... 0.02–0.1
Pulv. opii ..... 0.02–0.03
Potass. acetatis ..... 0.02–0.3
Sacch. alb. ..... 10.0
M. ft. pulv. S. One powder in a cup of tea at bedtime

—Graefe.

**Atonia Intestinalis.**—

℞ Sodii benzoatis,
Pulv. rad. rhei ..... āā 5.0
Pulv. nucis vom ..... 0.02
M. S. One powder two or three times a day.

—Huchard.

**Children's Emetic.**—

℞ Pulv. ipecacuan ..... gr. viiss.
Antimonii et potassii lactatis ..... gr. ⅙
Oxymel scillæ ..... ʒ iiss.
Aq. destill ..... q.s. ad ʒ i.
M. S. One teaspoonful every ten minutes.

—Baginsky.

**Tincture of Iodine in Diarrhœa of Children.**—Dr. Gosch (*Riforma Medica*) recommends the tincture of iodine in acute infectious gastro-enteritis in children, in doses of from two to four drops in sugar-water

every eight hours, for three days in succession. He claims it works promptly; the fever and diarrhœa cease, and the sensorium again becomes free. In adults in doses of six drops, three or four times a day, the result is not so rapid, but just as certain. He employs the following mixture:

℞ Tinct. iodi ..... 0.5
Syr. simpl. ..... 15.0
Aq. destill. ..... ad 150.0
M. S. One to two tablespoonfuls in the course of twenty-four hours.

**In Dry Pleurisy.—**

℞ Tinct. aconiti ..... ♏ x.
Spir. æth. nitrosi ..... ʒ ij.
Liq. potass. citratis. ..... ʒ iij.
Syr. tolutani ..... q.s. ad ʒ iv.
M. S. Two teaspoonfuls every hour.

**In Pleurisy with Effusion.—**

℞ Ammon. chloridi,
Ammon. carbonatis ..... āā ʒ i.
Tinct. cubebæ ..... ʒ iiss.
Syr. tolutani ..... q s. ad ʒ ij.
M. S. Teaspoonful in water every three or four hours.

—G. F. Butler.

**Diuretic for Children.—**

℞ Potassium acetate,
Potassium nitrate .. ..... āā gr. xv.
Oxymel of squill,
Comp. syr. sarsaparilla. ..... āā ʒ iiss.
Infusion of juniper berries. ..... ʒ ss.–iiiss.
M. S. To be taken during the day.

—Comby.

**London Cough Mixture.—**

℞ Ac. benzoici. ..... gr. xij.
Ol. anisi. ..... ♏ ij.
Spir. ammon. aromat. ..... ʒ iss.
Spir. æther. nitrosi,
Vini ipecacuan ..... āā ʒ iij.
Tinct. capsici ..... ♏ xx.
Glycerini ..... ʒ iv.
Infus. senegæ (conc.) ..... ʒ iij.
M. Allow to stand until clear and decant. S. Teaspoonful every three hours.

**Trigeminal Neuralgia.—**

℞ Extr. cannabis indicæ ..... gr. viiss.
Acidi salicylici ..... gr. lxxvi.
M. ft. pulv. No. x. S. Three powders daily

—Hirschkron.

**Coryza.—**

℞ Bismuth. subnit ..... ʒ i.
Pulv. camphoræ ..... gr. vi.
Pulv. acid. boric ..... gr. iij.
Morphin. hydrochlor. ..... gr. ss.
Cocainæ hydrochlor ..... gr. ¼
Pulv. benzoini. ..... gr. xv.
M. S. Snuff.

℞ Extr. hyoscyami ..... gr. x.
Potass. iodidi. ..... ʒ i.
Potass. bicarb ..... ʒ iij.
Extr. glycyrrh ..... ʒ i.
Aquæ anisi. ..... ʒ iiiss.
M. S. Dessertspoonful every four hours.

**Locomotor Ataxia.—**

℞ Ferri lactatis. ..... 2.55
Extr. cinchonæ ..... 4.0–5.0
Extr. nucis vomicæ. ..... 0.3–1.0

# Correspondence.

## OUR LONDON LETTER.

(From our Special Correspondent.)

CROONIAN LECTURES ON INSOMNIA AND HYPNOTICS—OBSTETRICAL SOCIETY—REPORT OF ROYAL COMMISSION ON THE DRINK QUESTION—COLLEGE OF SURGEONS—HASLOW HOSPITAL APPOINTMENT—CANCER SOCIETY.

London, July 21, 1899.

When it was announced that the Croonian Lectures would be delivered by Dr. Bradbury, I anticipated that the learned Cambridge professor would take the College of Physicians through some abstruse problems in physiology and chemistry. He has done so, choosing for his subject some points connected with sleep, sleeplessness, and hypnotics. He was known to have displayed great interest in the subject, and his researches are now before the profession. With regard to the nature and mode of action of hypnotics and the extraordinary results obtained by substitution of elements or radicals it must be confessed that the subject is hardly adapted for lectures, even before so learned an audience as the College of Physicians, but these audiences are seldom large and never so rude as to display symptoms of boredom, though now and then a fellow may be detected taking forty winks. The lectures have been published *in extenso* in the journals, and in due time will no doubt be issued in book form. They are certainly more adapted for quiet study in the library than for oral delivery. They are full of important facts and opinions on the action of hypnotics, and will repay all readers who master them. The latest discoveries as to the ultimate structure of nerve centres and elements are expounded in reference to theories of sleep, and brought to the consideration of the treatment of insomnia and the use of hypnotics in the light of clinical experience.

What, then, is this modern affliction—insomnia? Dr. Bradbury defines it "as a loss of the normal amount of sleep," that is, the amount normal to the individual, for, as is well known, people exhibit the most remarkable differences in this respect. Dr. Bradbury classifies the causes of insomnia as (1) irritative, (2) toxic, (3) psychical, (4) those arising from changed habits. Obviously under each of these may be ranged causes which may easily be removed when detected and others which are irremovable. Whenever possible the old rule to remove the cause is to be adopted, and the cases are excessively numerous when hypnotics are not called for and should therefore be shunned. Thus, among irritative causes, indigestion, teething, eye-strain, and other disorders are amenable to appropriate treatment, and only need to be diagnosed. But pain, even when the cause is known, is in another category. Again, psychical causes present similar differences. Overwork and irregular hours can be corrected. But grief, shock, and worry are too often beyond our advice or help. Coming now to special therapeutics, Dr. Bradbury's experience will furnish many suggestions to the perplexed practitioner. Passing by some of the most obvious, I may mention that a mild hypnotic will be sometimes required to interrupt the habit of sleeplessness. He recommends sulphonal or bromides. The latter remedy is also of special value in cases at the menopause. A bath or wet pack is mentioned as often useful in insomnia from overwork, especially if literary work. So a glass of grog, in those unaccustomed to it, Dr. Bradbury has found to succeed; but it seems a risky thing to advise, for are not these the very cases that often take to alcohol or drugs?

In pneumonia sleep usually comes at the crisis, but when it does not Dr. Bradbury has seen a hypnotic, such as paraldehyde or chloralamide, turn the scale in the patient's favor. These two are also useful in asthma. In bronchitis these and chloral are safer than opiates. The insomnia of heart disease may be benefited by digitalis, strophanthus, strychnine, and other cardiac tonics. Paraldehyde and chloralamide are most useful, but in some cases morphine may be required. When pain is the one cause of insomnia Dr. Bradbury pronounces morphine to be the best remedy, though he admits some of the synthetic analgesics have their value.

After the discussion on the fœtal pelvis of which I gave you an account, the Obstetrical Society turned to the subject of persistent mento-posterior position of face, introduced by Dr. Lewers, who related a case in which he had delivered a child alive by the axis-traction forceps. The progress of the labor had been for some time completely arrested, and ordinary forceps slipped as soon as the least traction was made. On using the axis-traction forceps the head came lower, and the chin rotated forward and was delivered in a very few minutes. There was a slight rent in the perineum, and the child had for some weeks a facial paralysis, but that disappeared.

Surgeon-General Harvey and Dr. H. Spencer took exception to the term "persistent," as the chin actually rotated when the axis-traction forceps was applied. Dr. Spencer also thought the axis-traction instrument rather dangerous in such cases, and ordinary forceps would give as firm a grip of the head if the handles were tied. He thought Luke Robinson's lever, which he showed to the society, better, as it would convert a mento-posterior into an occipito-anterior position. Dr. Lewers explained that by "persistent" he meant only that the chin had remained so long behind that the question of delivering the patient became urgent. Of course interference was not needed at an earlier stage.

Dr. H. Savory then read notes of a case of puerperal eclampsia accompanied by hæmoglobinuria and obstinate constipation. After nine days of loss of consciousness it was suddenly restored when a large fecal accumulation was mechanically removed. Dr. Savory had collected sixty-six recorded cases to show that copræmia was often present, and recoveries had sometimes followed purgative treatment. In his case not only were the bowels loaded, but the liquor amnii was full of meconium and of the consistence of thick jelly. Such conditions might be factors in the production or accumulation of an eclamptic toxin. The hæmoglobinuria might be due to excessive uterine efforts, just as excessive muscular exercise may produce it. A case was named of a lad who passed two pints of hæmoglobinuric urine after a run of ten miles.

Ten bulky blue books on the drink traffic are enough to form a library on the subject, and yet these ten volumes have resulted from the Royal Commission. The last is all report and extends to three hundred and eighty pages. The preceding tomes recorded the evidence brought before the commission. After all the noise of the conflict it is satisfactory to find a certain amount of agreement, although two reports are contained in the volume, one by the majority, the other by the minority. The need of restricting the number of licensed houses is admitted, and there are other recommendations for restraining the trade in intoxicants. It is proposed to make drunkenness a crime and habitual drunkenness a reason for granting a wife a separation order.

The fellows of the College of Surgeons may consider themselves specimens not only of obstinate conservatism, but of utter apathy as to the state of the college. I told you how they voted. Let me add that for the annual meeting of fellows there was again no quorum, so the president had to announce there was no meeting, although the council would have liked to hear the views of the fellows as to the proposed new charter. After the failure to get a meeting in January, 1898, the council reduced the two meetings a year to one, and the president suggested that after this third failure to get a quorum the council might think one meeting a year unnecessary. These apathetic fellows who cannot muster a quorum of thirty are the men who think members have no right to a vote, and leave the council to do as it pleases. It is high time for the members to enforce their will on the council by opposing the charter.

At the meeting of the council on the 13th, Sir William MacCormac was re-elected president. Mr. Howse and Mr. Tweedy were appointed vice-presidents. There is an undercurrent of dissatisfaction at the appointment of a deputy-inspector-general, over the heads of three full inspectors, to Haslow Hospital, our principal naval hospital. Mr. Goschen has been questioned in the House, and took the entire responsibility on himself, declaring he appointed the best man he could find. But he made no statement of his reasons for departing from the usual course, and it is said, by those who are the best judges of the special qualifications of those involved, that his selection is quite wrong, the men passed over having seen much service at home and abroad, while the lucky junior has passed most of his time in office work. You may remember the story of a bishop who was charged with nepotism for appointing his son-in-law to a living, and who coolly declared he was required to appoint a man who could do the duty, and that he knew this man personally and was sure he could, while as to others he had to trust to reports. I hope the first lord of the admiralty does not consider himself the best judge of medical qualifications, and that he has not, as is being whispered, been influenced by somebody outside the naval service. He did not state in the House that he had consulted the chief of the naval medical service.

The newly formed Cancer Society is displaying some energy. Dr. Snow gave an inaugural address which he entitled "The Cancer Fog," and compared it to Darkest Africa. Further he said, all the articles in lay journals on cancer and ninety-nine per cent. of those in the medical ones are vitiated by a radical fallacy—which is rather a strong statement and seems to touch the capacity of medical editors. The next move of the society was to request the government to appoint a royal commission. But the government has refused the request.

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 5, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 150 | 122 |
| Typhoid fever | 43 | 15 |
| Scarlet fever | 54 | 5 |
| Measles | 156 | 8 |
| Diphtheria | 155 | 19 |
| Laryngeal diphtheria (croup) | 1 | 4 |
| Cerebro-spinal meningitis | 0 | 11 |
| Chicken-pox | 8 | 0 |
| Smallpox | 0 | 0 |

**Duration of Isolation of School-Children for Contagious Diseases in Russia.**—The length of time during which the Medical Council of the Russian empire

excludes children who have been exposed to or who have suffered from an infectious disease is as follows: Scarlatina: After exposure, and without development of symptoms, an isolation of twelve to fourteen days is required. A child that has been ill may be allowed to return to school six weeks after the appearance of eruption, provided there is after that time no trace of desquamation. Measles: Fifteen days after exposure, or, in case the disease has been present, four weeks from the beginning of the eruption, if there is no trace of desquamation. Rubella: Sixteen days, or after two weeks from the beginning of the eruption. Varicella: Seventeen days, or after the fall of the crusts. Pertussis: Fifteen to twenty days, or after six weeks from the beginning of the cough, if kinks have ceased and there is no expectoration. Mumps: Twenty-two days, or after three weeks from the beginning of the parotid swelling. Diphtheria: Seventeen days, or three weeks after recovery, and after the disappearance of hyperæmia of the pharynx, larynx, and nose; if bacteriological examination is possible, only after the disappearance of the bacilli. Variola: Fourteen days, or after the fall of the crusts. All convalescent patients should receive two or three warm baths at 35° C. —*Medical Age*, March 25th.

**The Dum-Dum Bullet.**—Thursday, June 22d, says the London *Spectator*, was an exciting day at the Peace Conference, for a division was taken on the use of the Dum-dum bullet. In spite of the explanation of Sir John Ardagh, who showed that the effect of the bullet was not as represented, and that Tübingen experiments were entirely misleading, as they were not made with the Dum-dum bullet but with one totally different in construction, the whole of the non-Anglo-Saxon delegates condemned the British bullet and left Sir John Ardagh and his American colleague in a minority of two. Colonel Crozier, who firmly supported the British contention, proposed a very sensible general amendment, but this also was rejected. We need not say that Colonel Crozier, in acting with the British delegate, was simply obeying the considerations of justice and common sense, and was in no way backing up the British case because it was the British case.

**Alcohol and Insanity.**—At the present day, when an indulgence in alcohol poison is exerting its sad but dreadful effects on humanity, when our lunacy statistics show that the increase of insanity is really due to an increase in this vice, it behooves one to consider briefly the question. The recent publication of the London asylums committee's annual report shows an actual increase in lunacy in the asylums governed over and controlled by the county council of seven hundred as compared with last year. In one large asylum the medical superintendent states that out of nine hundred and fifty-eight inmates received two hundred and seventeen of these admissions were due to "intemperance in drink." One-fourth of the insanity then is attributed to a vice which is, so to speak, self-inflicted. These statistics also compare well with those issued by the lunacy commissioners, and on taking an average for the last five years, drink as a cause averages 20.9 per cent. of the admissions. When we take into consideration the fact that there is no disease whose germs are handed down to posterity to a greater extent than this, we shudder to think what the condition of the descendants of these alcoholic degenerates must be. It is a law of vital physiology that, as "like begets like," so do drunken parents often transfer their brutalizing habits to their unhappy offspring, who if they do not actually follow in the wake of their parents, exhibit some form of moral and mental obliquity or a nervous disorder clearly traceable to a deterioration of physical structure—in all probability seated in the brain—caused by a long and persistent indulgence in the use of intoxicating liquors. What Burton said years ago remains true at the present day, that "if a drunken man gets a child, it will never likely have a good brain." One of the leading physicians of America showed by his statistics that out of three hundred idiots whose history could be traced one hundred and forty-five were the children of drunken parents.—Forbes Winslow.

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ending August 5, 1899:

Smallpox—United States.

| | | Cases. | Deaths. |
|---|---|---|---|
| Florida, Jacksonville | July 23d to 30th | 4 | |
| Kentucky, Louisville | July 20th to 27th | 1 | |
| Louisiana, New Orleans | July 15th to 22d | 1 | |
| Ohio, Cleveland | July 22d to 29th | 7 | |
| Dayton | July 22d to 29th | 3 | |
| Pennsylvania, Philadelphia | July 22d to 29th | 1 | 1 |
| Pittsburg | July 22d to 29th | 1 | |
| Virginia, Portsmouth | July 22d to 29th | 4 | |
| Washington, Seattle | July 15th to 22d | 1 | |
| Tacoma | July 15th to 29th | 2 | |

Smallpox—Foreign.

| | | | |
|---|---|---|---|
| Brazil, Bahia | July 1st to 15th | 1 | |

## Original Articles.

### A TYPE OF TROPICAL FEVER.

By L. L. von WEDEKIND, M.D.,

UNITED STATES NAVY.

A VERY common type of tropical fever, which prevails at this place and over the islands generally (in the unacclimated), is known throughout tropical Spanish countries as calentura. It is of frequent occurrence, and will, without care on his part, attack the new arrival within a very short time. There are few if any prodromal symptoms. The onset is sudden—it may or may not be preceded by a slight sensation of chilliness, then a temperature of from 102° to 103° F. is noted. This continues, gradually increasing, until 104° or 105° F. is reached. There are general myalgic pains, cephalalgia, anorexia, and a very marked asthenia associated with gastric disturbance. With no treatment the case will convalesce within seven days. Quinine has no effect (that is, no specific effect). Large doses will, of course, reduce the temperature, but a low fever will continue for a number of days before it breaks. The cold bath reduces the temperature markedly, but temporarily.

During the dry season, in tropical countries, I have noticed this fever in every port I have visited. At first I used quinine in heroic doses, with no very gratifying results, being imbued with the "malarial infection idea" to the exclusion of all else. After a large but not very successful experience with this trouble, I met, in 1893, Dr. Stubert, formerly associated with the Nicaragua Canal expedition, but then in private practice in Managua, Nicaragua. To him I unfolded my tale of woe. He expressed no surprise, and suggested my abandoning the quinine entirely, and using in its stead aconite. The "malarial infection idea" died a hard death. To my entire satisfaction, I was sure of the cause of the fever; the results of my treatment, though in all cases eventually successful, bothered me considerably. At last I concluded that the quinine was of a very poor grade, in fact nearly useless. This knowledge satisfied me; and I used aconite as a substitute, poor indeed but necessary. The results were sufficiently pronounced to satisfy even me that in this one instance I was wrong.

Since that experience, whenever in tropical countries in the dry season, I use aconite in these cases with the most excellent results.

At this hospital, when the patient is admitted, he is given divided and frequent doses of calomel, until two or three grains have been taken. This is followed in the evening by a brisk saline purge. After the calomel he gets four drops of the tincture of aconite every two hours for three, four, or possibly five doses; the amount depending on the evidence of the drug's action. Within five hours, as a rule, the bowels are thoroughly cleared; the intense headache is somewhat relieved, and gentle perspiration is going on. The myalgia is marked, and I usually relieve it with an opiate at night. The next day, in the great majority of cases, the temperature is normal and so remains. A cold bath (or as cold as the water becomes here) is now given; the patient remains in bed for three or four days, as the asthenia is marked, and is then ready for duty. Some of the cases are a little obstinate, the temperature not remaining at normal, but running up as high as 101° F., and then falling to normal about forty-eight hours after admission, though the uncomfortableness is relieved by the aconite as by no other remedy.

Generally throughout the world the malarial fever of the tropics is dreaded, and very justly so; but malarial fever in the tropics in the dry season, though it does exist, is not the type of fever I have just described (though I have noticed that it is usually thought to be so). The calentura, the most common of tropical fevers (in the dry season), is, I feel convinced, non-malarial, and is due, I think, to exposure to the direct rays of the sun. What action then takes place I shall not presume to say; the result I have given you.

Among the present residents of Manila are many strangers, the families of officers, etc., all unacclimated. The female contingent do not expose themselves to the sun (complexion), remaining under cover until the cool of the evening. Many of the "convincible" men use white umbrellas or very large, light, and cool helmets when it is necessary to expose themselves to the sun; these do not suffer from the fever.

Many cases develop aboard ship in men who have not been on shore in many months, and when the ships are anchored at least a mile from shore.

All water used for drinking-purposes ashore is boiled, or the water is distilled aboard ship and sent ashore. The rains are commencing, and with them I look for the dreaded malaria.

With the use of a white umbrella, a large, light helmet, loose white clothes, and non-exposure to the sun, there will be no calentura. Exposure to the sun may be necessary, but the protection as above suggested in almost all cases will prevent the fever. The residents of the far East, in their greeting for the first time, invariably caution the newcomer: "Keep out of the sun; if you don't you will have the fever." Manila in the dry season is a healthy place. Now that the city is clean, we can almost suggest it as a health resort. Patients with malarial poisoning arriving here develop the fever, and the enervation resulting from a long residence here without change renders convalescence in these cases exceedingly slow.

My search for the plasmodium has in all cases been negative.

UNITED STATES NAVAL HOSPITAL,
CAVITE, PHILIPPINE ISLANDS, May 29, 1899.

---

**Thrombosis of the Sigmoid Sinus.**—Dr. Gorham Bacon (*New York Medical Journal*, July 8, 1899) drew attention to the following points: (1) The impropriety of giving antipyretics in all cases of suppurative otitis media; (2) the value of a bacteriological examination of the secretions from the external auditory canal in all cases of suppurative otitis media; (3) the importance of operating at the earliest stage possible after the diagnosis of thrombosis has been made; (4) the use of the decinormal saline solution during the operation for sinus thrombosis or immediately following it.

# ON THE RÔLE OF PRIMARY AND SECONDARY OSTEOPLASTIC SURGERY, IN THE TREATMENT OF COMPLICATED OR COMPOUND FRACTURES OF THE EXTREMITIES.[1]

BY THOMAS H. MANLEY, M.D.,

NEW YORK,

VISITING SURGEON TO HARLEM HOSPITAL; PROFESSOR OF SURGERY, NEW YORK SCHOOL OF CLINICAL MEDICINE.

MODERN advances in the sciences have rendered necessary for accuracy an entire recasting of our methods of dealing with various disorganizations of the bones, of whole limbs, or their members, produced by the effects of violent force.

Very much more circumspection and deliberation are demanded of the surgeon before he proceeds to sacrifice a limb or any part of it, by amputation, than in former times; improved mechanical expedients, with a widened knowledge of the regenerative properties of bone tissues, have enabled us to hold out hopes to spare and to restore, in varying degrees, many a limb which in the near past was irrevocably condemned to severance from the body; and more, in trying cases when the extent of mutilation of the soft parts has been considerable, when perchance articulations have been opened, or there has been such extensive shattering of the bone that all our energies are concentrated on saving the member regardless of the degree of resulting distortion or deformity, by resorting to subsequent osteoplastic procedures we may at present very frequently succeed in restoring symmetry, joint action, and muscular movement.

**Conditions Essential for Success in Primary Osteoplastic Procedures after Serious Fractures of the Extremities.**—First, the condition of the patient manifestly is our most serious concern. Is our patient in the state of grave physical shock? I say physical shock because one may underestimate the degree of great collapse which follows various serious crushes of the body, when the senses are unclouded and the unfortunate patient is sanguine of an early recovery, and besides entertains no serious thoughts of approaching death, as this comes only when the surgeon intimates that the traumatism is extremely grave, and that no time should be lost in adjusting his temporal affairs and preparing for death

Let it be remembered that the mental attitude of the patient weighs for nothing in reaching a prognosis with this class.

Second: Has the patient been greatly exsanguinated? Great loss of blood is always a very grave element in all extensive mutilating injuries. Our patient is blanched and cold; the pulse is thready, traumatous, and irregular, and the patient is thirsty; the muscles of the face twitch and the eyes are sunken. We will do well to direct all our energies toward reviving the waning powers of life before anything like a critical examination of the mangled parts is undertaken.

Third: Is there evidence of coexisting internal hemorrhage, or serious visceral injury? In many mangling wounds of the limbs from machinery or railroad accidents, the nervous system suffers violent shock, the whole body severe concussion, and simultaneous visceral complications are not very infrequent. We will certainly not minutely examine into the character of an injured limb, while there are signs which point to the grave implication of an organ vital to life.

From the foregoing it is therefore apparent that under all circumstances our first attention must be directed to the individual; he must be made comfortable and composed, and, if ground for hope remains, artificial heat must be utilized and he should be freely stimulated. Full reaction should be established before a thought is entertained of ulterior treatment of the limb.

**On the Period when it is the Safest and Most Expedient to Institute a Critical Examination of the Parts, with a View of Deciding on the Line of Treatment to be Adopted.**—It has long been my conviction that very much harm has often been inflicted by the premature rough handling of limbs before the effects of shock have passed off. In serious cases our primary efforts should be directed toward, first, securing effective and permanent hæmostasis; second, thoroughly cleansing and covering the parts; and third, placing the limb in a comfortable position. The word comfortable is here emphasized because at this time theories must give way to facts. The limb is in the proper position when a sense of ease is experienced. This follows when the pressure on the nerve trunks is relieved and every impediment to the free movement of the blood current is removed.

To force into full ether coma one suffering from a badly mangled limb, and then make violent and repeated movements of torsion or extension, is greatly to imperil his chances, and is calculated surely to circumvent Nature's efforts at restitution. But when the injury is not one of great magnitude and the patient's general condition is good, we may be allowed more latitude of action, and more lengthy manipulation may be permitted, although there is no doubt that, in a general way, the practice is a bad one of making the first examination very long, or commencing any operative procedures of a protracted character at this time. We have done quite enough, then, at the first dressing when we have controlled hemorrhage, embalmed the limb, and comfortably adjusted it.

How long should we wait? If there be no secondary hemorrhage, no fresh exacerbation of pain, and no signs of asphyxiation or gangrene in the limb, we may delay for forty-eight hours or more with advantage before we remove the primary dressings. Now, at this stage we can see where we are, we can accomplish what was impossible at the primary dressing, we can determine the extent of osseous vitality, we can form some estimate of what the future possibilities are for the limb. The time has now arrived when we may determine our course of action, though there is no good ground for haste yet, in the adoption of definite therapeutic measures. As processes of repair can commence only on the subsidence of acute inflammatory engorgement, the prospect of effective osteogenesis by this course is enhanced. And, furthermore, our patient, now fully restored from the immediate depressing effects of violence, is better able to support with success further operative measures.

**Secondary Osteoplasty after Reparative Processes Are Complete.**—This constitutes a new, large, and growing field for progressing surgery, the scientific foundation of which was laid by the celebrated Ollier, and its practical utilization has been consummated by aggressive investigators in Europe and America. By judicious and skilful osteoplasty it is astonishing what may be accomplished in the way of correcting deformity and improving and restoring function in damaged limbs; in restoring animation in parts palsied by nerve inclusion or nerve pressure. Alone or combined with tenotomy or arthrotomy under proper conditions, its use in enhancing the working value of the limb cannot be overestimated. By the intelligent employment of osteoplasty we may often not only prevent an amputation, but transform a wasted, twisted, ankylosed limb into a useful member, as it has several times been my good fortune to be able to demonstrate.

**Conditions which Lead up to the Necessity of Secondary Osteoplasty.**—It might be supposed at

[1] Read at Richmond, Va., June 2, 1899, before the International Association of Railway Surgeons

first sight that if a bad fracture or fracture-dislocation was properly adjusted and treated immediately after injury, there would be no occasion for any sort of consecutive operations; that the time for interference or precise action was while the tissues were disorganized, the sooner after the accident the better. But such reasoning is fallacious, as every experienced surgeon will know. Many times the question we have to solve is not, Can we save the limb with a good prospect of recovery?—but, Can we by any means within our reach preserve it in any shape? In very many fractures of various descriptions and under various circumstances, no sort of fixed mechanical adjustment is possible; as, for example, when a fracture is multiple, there are internal injuries or the vascular channels have suffered serious harm, and asphyxia of the limb is pending.

**Open and Closed Fractures; or the Complicated Simple and Compound Fractures.**—My own investigations and experiments on induced fractures in the limbs of frogs, as well as clinical observations on mutilated limbs, have convinced me that incomplete vascular stasis of the distal end of a mangled limb is entirely compatible with its ulterior vitality, provided only that the damage to the great trunks has not been too great. But how can we calculate the vascular damage, or what shall be our guiding principle of action if we are assured of its existence in this class of cases? There are no means by which an estimate of vascular damage can be primarily determined, and often it is several days before the full vascular tide has begun to move. Our guiding principle, then, must be not to strangle or paralyze the already crippled circulation. No sort or description of splint or constricting bandage should be adjusted until the circulation has been fully rehabilitated.

It therefore follows that inasmuch as accurate mechanical adjustment is not possible or expedient, here faulty, defective, distorted limbs or non-union may follow. We may also have hyperostosis or osseous fusion of continuous symmetrical shafts, and other accidents.

This, then, would constitute the second class; *i.e.*, those cases of compound fractures in which it is obvious enough in the primary dressing that osteoplasty is called for; but for various local and constitutional circumstances beyond our control it is deemed advisable and sometimes imperative that we delay until the work of union is advanced or completed.

Complicated simple fractures or fracture-dislocations are not infrequently followed by such a degree of deformity or loss of function as seriously to interfere with the future of the limb. This is notably the case in various types of Pott's or Colles' fracture, of fracture of the humerus, its shaft or proximal or distal ends, intracapsular fracture at the hip joint, fractures of the patella, etc. In many of the cases belonging to the above class osteoplastic surgery may be frequently utilized as a secondary or consecutive procedure; rarely immediately after injury, except in sundering of the patella. The tendency of most fractured bones is to resume their normal position after replacement, provided muscular tension can be effectively overcome when satisfactory results follow; but in various situations, especially when joints are involved and the apophyses are broken off, complete replacement and support at the primary adjustment may be impossible, or if effective then the fragments may later move out of position and require operative treatment.

**On the Question of Converting a Simple into a Compound Fracture, for Purposes of Diagnosis or Treatment. Is it ever Justifiable?**—It had long been taught that compound fractures require about twice as long a period of time to unite as simple fractures; and besides, that this type of fracture was always a much more serious affair than in those breaks of bone in which the integument remained whole. Until Macewen demonstrated the safe and simple osteoplastic method of speedily correcting deformed and distorted bone shafts, surgeons were about as chary of cutting into healthy bone as they formerly had been about opening the cavity of the peritoneum. They had a horror of making a simple a compound fracture; and when a considerable deformity followed a severe simple or compound fracture, they were usually content to leave it undisturbed, or if the deformity was considerable with the joint locked, they amputated the limb.

No one should ever lightly undertake an osteotomy after fracture, but when the condition is such as will inevitably be succeeded by marked deformity of the limb with serious impediment in function, we should never hesitate to open freely down on the seat of osseous disorganization and deal with the case as existing conditions require—provided, always, that the most rigorous asepsis is enjoined and we have a proper appreciation of the difficult task before us.

It is certainly a mistake to assume that all compound fractures are more protracted in uniting than all so-called simple fractures. Many simple fractures near articulations may be treated without splinting or compression of the vessels, united by primary union. Heretofore, when an avenue for infection was maintained by what was known as "drainage," and when the fragments were kept in the vise-like grip of rigid, unyielding adjustments, and thereby the vascular system was nearly palsied, surely enough tardy or imperfect union was the rule.

Compound-fracture wounds were formerly quite invariably drained. Prophylactic drainage had indeed been regarded as a surgical dogma in open fractures, as in open wounds of nearly every description, whether they involved cavities or not. But we have now been convinced that indiscriminate drainage is a bad practice, and that in an aseptic or a recent wound in healthy tissues "drainage" is worse than useless.

It therefore follows that in recent compound fractures not attended with extensive laceration or contusion of the soft parts, and an absence of shattering of bone, the overlying tissues may be closed in with or without suture, and prompt primary union of the fleshy and the bone tissues may follow.

Incision through the overlying tissues for purposes of diagnosis in fractures is certainly not justifiable except in those involving the skull.

By the use of the *x*-rays and other expedients, a therapeutic diagnosis is practicable in all fractures. Free incision, therefore, in many fractures is permissible for purposes of treatment—osteoplasty; never for diagnosis only, except in skull fractures.

**The Scope of Secondary Osteoplasty in Defective Joints or Deformed Limbs after Fracture.**—Secondary osteoplasty judiciously utilized will often yield remarkable results, and may be regarded in traumatic surgery as one of its most salutary achievements. It deals with bones after their fragments have united, when the nerves are caught or compressed; in a hyperostosis, when the shafts are greatly deflected—in fact, when the limb is crooked and deformed; when a joint has been involved and its motions are either greatly impeded or entirely lost. It is an invaluable resource in the pseudarthroses. Among the joints its great value is at the hip, the shoulder, or, above all, at the elbow. Stimpson has utilized it with advantage after union and deformity at the ankle in Pott's fractures. Secondary osteoplasty, however, may be employed with great latitude on the bone shafts of the extremities; with the greatest advantage on the leg. The sooner after union and the younger the patient the better. It is almost marvellous what we may accomplish by os-

teoplasty in the bones of growing children, as was recently demonstrated by Heuter.[1] In a fracture of the humerus in a patient five years old, attended with considerable loss of bone and fluid in the joint, he turned to the skeleton of the thorax of the child and resected a section of the fifth rib, embedded it in the hiatus in the arm, and closed the wounds. Union was rapid and complete. In nine months the full use of the arm was restored and the rib regenerated. This indeed would seem the climax of homologous osteoplasty, and suggests what is expected of the surgeon in our times in the management of serious fractures.

It is not recommended that recourse be had to this means in cases of moderate deformity of a limb with but slight impediment in function. But there is quite a large margin of cases of stiff or useless joints with bowed bone-shafts or useless limbs following union, in which osteoplasty will sometimes accomplish extraordinary results. By it the muscles are liberated, and with the free division of the adhesions in the soft parts pressure on the nerves and blood trunks is removed, and the wasted, painful, paralyzed, and useless member recovers its lost vitality. There has been practically a resurrection, the dead or useless has again come to life.

In medico-legal cases in the future, when serious fracture cases are to be considered, or when the future working value of a limb is to be estimated, the question as to whether the full resources of osteoplasty have been exhausted must be answered before it will be possible to make any definite calculation as to what the extent of permanent injury is.

**Osteoclasis, and Osteotomy with Osteoclasis, in Angular Deformity of the Thigh with Shortening following More or Less Imperfect Union after Fracture.**—Every surgeon or practitioner having much experience in the treatment of fractures of the femur will occasionally meet with cases of marked angular deformity resulting, after union, with considerable shortening of the limb.

It is important to note here that it is not so much non-union which is at fault as imperfect or mal-union. In some of these cases there may be ground for suspecting unskilful treatment, but in the majority of cases the fault is with the patient, and is fundamentally constitutional. We know that fractured bones sometimes play strange freaks, at one time non-union lingering indefinitely; but the limb is massaged or some internal remedy given, when all at once we note that consolidation has set in.

Reches recently notes how in a few cases of tardy union he administered thyroid extract with the most remarkable effect, while in several others it was quite useless. Again, in some cases after a month or more we release the limb from the splints, and find the limb in excellent outline with little or no shortening. There seems to be good union. We allow the patient to go about on crutches, later with a cane, and finally lose sight of him. But he turns up with a deflected, distorted limb, shortened and crippled. At first sight the aspect of such a case has a most disquieting effect. The patient has had his limb again "measured," and tells us perchance that we left him a hopeless cripple. The prospects of having to defend one's self in civil action is not the most agreeable contemplation after such a mishap. In this class the patient reports only late, after the hardening process is advanced—say from six months to a year; then probably nothing less than a formidable operation will hold out any prospects of overcoming the deformity. But happily most of these cases are in rickety subjects, or those in whom the callus softens and yields after the surgeon has discharged the patient, when weight is put on the limb. However, the bowing may occur before the patient has left the bed. In all these cases, immediately after discovery of the deformity we should insist on osteo-resection with or without osteotomy.

In my experience the deflection of the femur has occurred in children most frequently. It occurs most commonly in fractures near the middle of the femoral shaft. The convexity of the deflection is outward in nearly all cases. It is interesting to note that in the great majority there is little if any overriding of the fragments, as we know from the fact that after we refracture or press the shaft back into line there is generally no shortening.

When these cases are seen early, there is no class of deformities treated with more gratifying effect, with more security and certainty of results. In all, there must be complete osteoclasis or refracture as soon as discovered, when the deflection is completely overcome. An adjustment should then be applied, but should be frequently removed in order frequently to bathe, massage the limb, and freely move the joints. In some cases refracture of the femur is easy without dividing the bone, even more than a year after the original injury.

Such a case came under my care some years ago. The patient, a woman aged forty years, was injured by a defective hinging. She had a complete fracture in the middle third of the left femur with but very little shortening. The limb was adjusted in gypsum, and after a week she was taken home. About a year after, when the action was tried for damages, her physician came to me and told me there was four and one-half inches of shortening, and that walking was impossible. She had then won her suit with a liberal verdict. Six months after this I was sent for to deal with the deformity. Now, at more than eighteen months after fracture, the femur was readily refractured and pressed into place. In three months union had completed without any shortening. She at present has perfect use of the limb without the slightest trace of any defect in locomotion. It is now three years since the deformity was rectified.

Osteotomy, as a preliminary step to osteoclasis, is indispensable when the uniting bond of osseous tissue has undergone hardening and does not yield to the application of moderate force. Macewen has shown us that osteotomy for rickety thighs or legs in children is a procedure quite devoid of danger, and is the most valuable adjustment for the correction of deformed limbs ever placed at the command of surgeons.

We should not be slow to take advantage of it in those distortions following union of the diaphyses, when it becomes necessary to cleave or partly divide the bone, though it should be borne in mind that in those cases of aggravated deflection we have to deal with an excessive callus formation besides highly vascular parts; and, moreover, that in the femur of the adult osteotomy is always a procedure of considerable gravity. It is wiser, however, when ossification is advanced, to resort to it rather than risk great violence by force, and thereby inflict serious damage to the large blood trunks, the nerves, and soft parts. In its performance on the adult its greatest danger may be obviated by effective economy of blood and the most rigorous asepsis.

[1] Wiener klinische Rundschau, March 12, 1899.

**Urinary Antiseptic.**—Methylene blue has proved of service in my hands on several occasions. Taken in two- or three-grain doses three times a day it exerts a markedly antiseptic effect, coloring the urine a greenish blue. Its disagreeable tendency to cause intermission of the pulse must not be forgotten in prescribing it, and I have one case to record in which it gave rise to profuse diarrhœa which ceased only upon withdrawal of the medicine.—A. R. Elliott.

## ANGIONEUROTIC ŒDEMA: WITH A REPORT OF FOUR CASES.

By HERMAN B. BARUCH, B.S., M.D.,
NEW YORK.

This peculiar affection has for many years been carefully studied by competent observers, but as yet very little is known of its etiology and pathology. The disease has been described under very numerous titles, some of which follow: Angioneurotic œdema, giant urticaria, urticaria tuberosa gigantica, localized transient œdema, œdema glottidis neurotica, fugitive cutaneous œdema, acute non-inflammatory swelling, vasomotor œdema, acute circumscribed œdema, acute essential œdema, acute periodical swelling, ephemeral congestive cutaneous tumors, acute circumscribed cutaneous œdema, creeping œdema.

A glance at these various titles will show most of the prominent symptoms of the disease. It was first described and studied by Quincke and his pupil Dinkelacker.

Quincke regards a suddenly increased permeability of the capillaries as the essential etiological factor. Collins' very careful and thorough article gives an excellent description of its course and symptoms and contains much valuable statistical information. Osler, Matas, Jamieson, Graham, and Rupert Norton have also made most valuable contributions to this subject.

No age seems to be free; it attacks both sexes, and its etiology is very varied. Heredity is here given a most prominent rôle by Osler. He reports the history of a family embracing five generations of which twenty-two members had been affected. In the four cases observed by me, no family history of anything resembling this affection could be elicited by the most careful inquiry.

It seems to present a remarkable periodicity in its onset. In Matas' case the attacks came on with unfailing regularity between eleven and twelve o'clock A.M. Gervaert reports the case of a boy three years old, with pertussis, who had regularly recurring tumors (evanescent) of the neck, in the afternoon of three successive days. The attacks in one of my cases occurred regularly every morning on washing the face and hands with cold water.

This brings us to the discussion of the exciting causes. Very frequently it is absolutely impossible to assign any reason for the sudden onset of an attack. It usually comes on in the early morning hours when vitality is at its lowest ebb.

Mental and physical overwork, gastric and intestinal irritation, are the chief predisposing causes. Often exposure to cold will cause the lesions to appear at once. The ingestion of strawberries, apples, oysters, lobsters, crabs and other crustaceæ, poisonous articles of food, toxic products as tobacco, alcohol, and certain drugs, will in a susceptible individual produce the lesions of giant urticaria. One attack predisposes to another. They often follow in a continuous series, cease altogether for some months, and then reappear.

The symptoms are very varied, and, with the exception of the characteristic skin lesions, very inconstant. These are non-inflammatory in character, rounded or oval in outline, and elevated above the level of the surrounding skin surface. They vary in size from one-quarter of an inch to four or five inches in diameter, and frequently will involve an entire extremity. Often a lesion appearing on an extremity will gradually extend, maintaining the same width, until it "creeps" off the end of the extremity and disappears.

They are often not colored, but frequently are iris-hued and sometimes contain numerous small hemorrhages which remain after the swelling disappears. This takes from a few minutes to several days or even two weeks. The face and extremities are the favorite seats; the hands being most commonly involved. The penis and scrotum in males and the labia majora in females are next most frequently involved. The lips and cheeks often swell to enormous proportions. There is one form in which the tongue is chiefly involved. This seems to be often the sequel to the ingestion of strawberries. There is no doubt that the various mucous surfaces are subject to the same sudden œdema, and this causes the numerous gastric and intestinal symptoms. Frequently an attack will be ushered in by severe colicky pains in the epigastrium. These last for some time, then as suddenly disappear. The wheals appear on the general body surface. The patient often vomits and purges, and then is perfectly well again. Often mental depression and incapacity for work are marked. One of my patients, a prominent lawyer, was absolutely unable to work during the attack. There were great inability to concentrate the attention and lack of interest, together with depression bordering on melancholia. There was always great dread that the attack would end fatally.

After the lesions disappear the skin returns to its normal condition, no trace of the swelling remaining. This is also true of the mucous membrane of the stomach and intestine. The pulse is increased in frequency during the attack; the temperature sometimes rises to from 100° to 101° F. There is a marked sense of tingling and burning in the lesions, but very seldom itching. The tumors are hard and unyielding and do not pit on pressure. When the swelling is diffuse the tension is not so great.

Mettler reports a case in which œdema of the pharynx and larynx was most marked. These cases are very dangerous, as asphyxia may occur during an attack. Sometimes bleeding occurs from the mucous surfaces, as from the bronchi and into the conjunctivæ, with hæmatemesis and melæna. Hæmoglobinuria has been reported but is very rare. Of Collins' seventy-two collected cases thirty-four per cent. exhibited gastro-intestinal symptoms, twenty-two per cent. had throat symptoms. During the attack patients often have an insatiable thirst. The intestinal colic is often so severe that even large doses of morphine give little relief. The urine is voided in large quantity after the attack, which often leaves the patient completely exhausted and in a state of extreme nervous tension and anxiety.

Often the patients present stigmata of hysteria, such as areas of anæsthesia, etc., and have other manifestations, as hystero-epilepsy, neurasthenia, and various reflex symptoms from the nose, uterus, ear, stomach, etc. Hence it would seem that these cases are really hysterical explosions in which the pent-up nervous energy is expended not in muscular contractions, convulsive movements, and loud cries, but upon the vasodilators, causing an increased capillary area and permeability of the vessel walls, thus rendering possible the sudden formation of these tumors and œdema so characteristic of giant urticaria. Just as the wildly excited hysterical patient returns suddenly to the normal, leaving no trace of her former condition, so does the disturbed circulation return to the normal with the sudden disappearance of all symptoms due to the disease, leaving the skin and the vessels just as they were before the attack. The analogy is certainly very striking.

Complete though infrequent autopsies show no trace of lesion in brain or spinal cord, peripheral nerves, or circulatory system. This is one more fact in evidence of the truth of Stoke's dictum that "there is no single nervous symptom which may not and does not occur independently of an appreciable lesion of the brain, nerves, or spinal cord."

The treatment has so far been very unsatisfactory. Pilocarpine, which has given such brilliant results in

urticaria, has some control over this form, but will not prevent recurring attacks. The most that can be done for such patients is to put them in the best possible physical condition, and do what we can to maintain this status. Gastric and intestinal derangements should be carefully corrected. In this as in most other intestinal conditions, calomel has proven to be the nearest approach to an intestinal antiseptic. Of course, when there is a direct relation of the attacks, as there not infrequently is, to the ingestion of certain articles of food as shellfish, strawberries, etc., and indulgence in alcohol and tobacco, abstention from these will give freedom from the attacks.

The tonics, as iron, quinine, strychnine, arsenic, etc., should be used when indicated. Galvanism, faradism, and static electricity, as well as judiciously applied hydrotheraphy, have a wide field of usefulness here. All attempts at heroic methods should be carefully avoided.

The prognosis as to recovery and freedom from attacks is bad. The attacks may not occur for months or years, and the patient regards himself as cured, but suddenly they recur. The prognosis as to recovery from rhe individual attacks is excellent, although some cases of death from œdema glottidis and pulmonary œdema have been reported.

The following are reports of four cases which have come under my own observation.

Case I.—Mr. S——, aged fifty-nine years, has always been well. There is no family history of such attack or of any neurotic taint. He has a very florid complexion; he has taken a cold plunge every morning for many years. He does not use alcohol or tobacco; there is no history of syphilis or gonorrhœa; he is very excitable, and flies into a violent rage on the slightest irritation, although stern and calm in demeanor on ordinary occasions. His pulse is full, and the arteries are soft and yielding. There are no gastric symptoms; the bowels move from two to three times a day. Three years ago he noticed after coming from a surf bath that his hands and feet were warm and "tingled"; they felt stiff but did not swell. This was repeated on several occasions, and he stopped the surf baths and noticed nothing more until this spring. He had in the mean time continued his morning cold plunge. I saw him one morning about six months ago. Immediately after coming from his cold plunge he noticed that his hands began to swell until they became three times their normal proportions; the joints were tense and immovable, and the wrists were also involved. They were of a dull red color, very tense but not glossy, and did not pit on pressure. There was an intolerable sense of burning and tingling. The feet were also swollen, but not to the same extent. The inner sides of the thighs were œdematous. The scrotum and penis also assumed larger proportions, being very tense and swollen. The pulse was 100, the temperature 98.6° F. The urine was found of clear reddish color; specific gravity, 1.025, strongly acid; it contained neither albumin nor sugar. The microscope showed numerous uric-acid crystals. The blood was examined for plasmodia, but the result was negative. These symptoms disappeared in the course of two hours, the skin regaining its normal condition. Although there seemed to be a direct relation between the cold plunge and the appearance of the skin lesions, it was determined to prove this beyond a doubt by repeating the bath next morning. This was done with a recurrence of the same symptoms. Pilocarpine gr. $\frac{1}{10}$ did not seem to hasten the disappearance of the lesions. The patient was advised to discontinue his morning plunge, was given strychnine gr. $\frac{1}{30}$ t.i.d., and forbidden meats and sweets. An alkaline mineral water ℥ viii. every two hours, was ordered, with the view of correcting the urinary conditions. The next morning the patient did not bathe, but washed his hands with cold water. The hands immediately began to swell. The rest of the body remained normal. He was then advised to dip the hands in cold water frequently during the day to see if an attack would be precipitated, but this test proved negative. Bearing this seeming periodicity in mind quinine was administered, so that he was thoroughly cinchonized at the time when his bath was due. This was repeated for three mornings, when a cold plunge was again followed by a complete attack. This showed conclusively that notwithstanding the periodicity of the attacks quinine had no control over their recurrence. The diet and general *régime* were continued for several weeks, a warm bath replaced the cold plunge, and the patient had no recurrence. The urine was again examined and found neutral in reaction, specific gravity 1.010, no uric acid, no albumin, no sugar. The cold plunge was resumed and was followed by no unpleasant effects. During the summer he bathed frequently in the surf, and at this writing has had no recurrence.

Case II.—J. M——, a prominent lawyer, aged sixty-eight years. Family history is negative. For the last eight years he has noticed that at intervals his tongue swells so that it fills the mouth entirely. Speech is impossible; breathing is extremely difficult, and the throat is tense and painful. These attacks always come on in the early morning hours and often arouse him from sound sleep. The tongue remains swollen from two to three hours, and when improvement commences the swelling disappears in the course of fifteen to twenty minutes. These attacks are always accompanied by great mental and physical depression and fear of impending death, he remains depressed for several days. At first the attacks were separated by intervals of two to three months, but are now becoming more frequent, occurring every seven or fourteen days. They are unaffected by treatment. The urine is negative. There are no gastric or intestinal symptoms. After careful search, no especial cause could be found for the individual outbreaks. There were no cutaneous lesions.

Case III.—Dr. S. V. H——, aged twenty-eight years. His family history is negative, previous history negative. While in the last year of his medical course he was under great additional mental strain caused by the severe illness of his brother, and his general condition was very much depreciated. He had been constipated for three days, and awoke one morning at three A.M., and found his penis and scrotum considerably swollen and the seat of intense burning and tingling. He applied cold compresses, but in spite of this the organs continued to swell until, as he expressed it, he was afraid they would burst. This continued for two hours, when the swelling gradually subsided, leaving the parts perfectly normal. That afternoon there appeared, midway between the elbow and wrist, a ring about two inches wide and raised about an inch and a half above the surrounding tissue. The skin was tense, did not pit on pressure, and was of a dull reddish hue. This ring gradually advanced down the arm to the hand, involving each of the fingers to the tip, and disappeared. A brisk cathartic was followed by several large offensive movements, and the symptoms have never recurred.

Case IV.—J. S—— , aged thirty-five years. The family history is neurotic; there has been no case of the same kind. Previous history: Five years ago he had the first attack; since then he has had an attack each year.

Present history: He had been constipated for several days, and one night noticed that the arms and legs tingled and itched. Small white spots about one-quarter of an inch in diameter appeared on the general body surface. These were surrounded by a red areola

about one-half inch wide, and were elevated above the surface of the skin. They increased in area until, as the night progressed, they assumed the proportions of six to eight inches in diameter. Nausea commenced early and was progressive. Intense abdominal cramps appeared which were not relieved by large doses of paregoric. The next morning there was an intolerable sense of heat and tingling in the hands and feet, which were enormously swollen and œdematous, but did not pit on pressure. The penis and scrotum were also swollen and distended. The tongue was not involved. The voice was clear, and deglutition was not difficult. The eyes and lips were puffed and prominent. The patient fainted twice during the second night, and twice during the succeeding day. A large dose, gr. x., of calomel followed by a saline purge produced frequent and very offensive stools. This purgation was followed by a rapid disappearance of all the symptoms.

It would seem that these last two cases were distinctly traceable to intestinal auto-intoxication, and it would in my opinion be the first indication, in the individual attacks, to cleanse the intestinal canal thoroughly.

Hotel Majestic

## THE USE OF QUININE IN MALARIAL HÆMOGLOBINURIA.

By S. L. J. STEGGALL, M.D.,

Port Limon, Costa Rica

While the effect of quinine in the treatment of malarial hæmoglobinuria is under discussion, the report of a few cases may not be void of interest. On the coast here we have many cases, although they bear a very small proportion to the enormous number of intermittent and remittent fevers.

The cases I shall quote are three, in which hæmoglobinuria came on while the patient was under treatment with quinine, and under further treatment the hemorrhage was stopped and the patient relieved. In these three cases the patients had been for years suffering from malaria, and had been in the habit of taking heavy doses of quinine, which, to a great extent, had lost its effect, hence the very large doses of quinine which were exhibited. Cases I. and II. I have treated at intervals for the last five years.

Case I.—Remittent fever with hæmoglobinuria. D. H. J ——, aged forty years, American, from Matina Lagoon. Past history: Has in the last four years had five severe attacks of malaria with hæmoglobinuria.

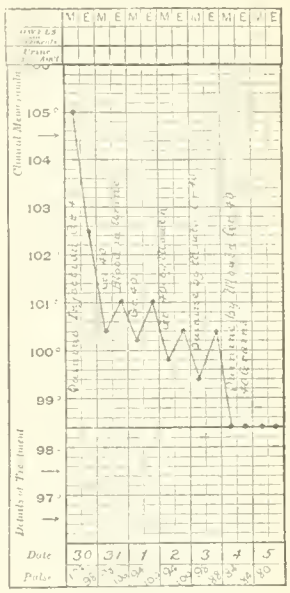
Present attack: Patient has marked malarial cachexia, has had fever, and been in bed for four days.

January 30th: A.M., T. 105°, P. 104. The patient feels very weak and bad. Is unable to retain anything on his stomach. Urine clear. ℞ Calomelanos gr. x., given in 1 gr. tablets; podophyllin gr. i., given in ¼ gr. pills. ℞ Hypodermic injection into each buttock of ℥ iss. of a twenty-five-per-cent. solution of acid hydrobromate of quinine (gr. xlv. in all). Also two injections of ℞ digitalin gr. $\frac{1}{100}$, strychnine gr. $\frac{1}{50}$; mustard plaster applied to pit of stomach. P.M., T. 102.6°, P. 98. Urine clear. Bowels acted well after two enemata of soap and water.

January 31st: A.M., T. 100.5°, P. 98. Quinine injection, gr. xl. Digitalin and strychnine injection. Patient kept down milk and soda water. Bowels open. P.M., T. 101°, P. 106. Slight chill with hæmoglobinuria.

February 1st: A.M., T. 100.2°, P. 94. Slight darkness of urine due to hæmoglobinuria (spectroscopic test used). Quinine injection, gr. lx. Injection of ergotinin, gr. $\frac{1}{100}$, twice. P.M., T. 101°, P. 100. Urine clear, no albumin.

February 2d: A.M., T. 99.8°. ℞ Quininæ gr. xl. P.M., T. 100.2°. Urine clear, no albumin.



Case I.

February 3d: A.M., T. 99.4°. P.M., T. 100.4°. ℞ Quininæ acid. hydrobrom. gr. xl. (by mouth).

February 4th: A.M., T. normal. ℞ Quininæ acid. hydrobrom. gr. xl. per diem. ℞ Ferri pyrophosphatis gr. v., liquor arsenicalis ♏ iv., digitalini gr. $\frac{1}{200}$, strychninæ gr. $\frac{1}{100}$, aquam ad ℥ i. M. Sig. Four times a day. There was no relapse; no further rise of fever.

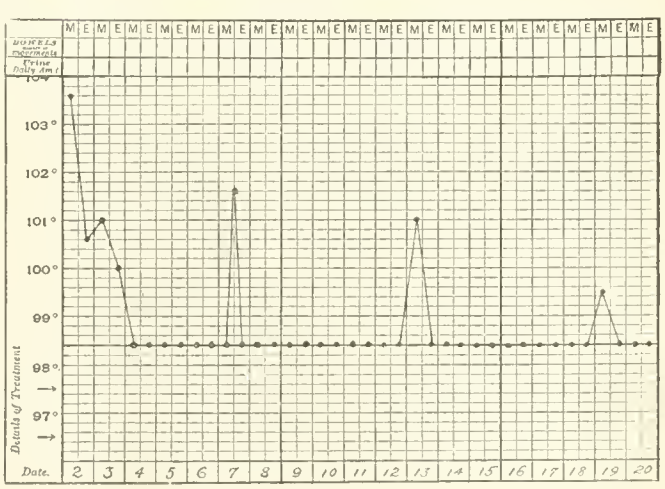
Temperature chart by Mr. George Charles Coles, M.R.C.S.

Case II.—E. T——, aged ten years, white, American, from Matina Lagoon. Hæmoglobinuria with periodic attacks.

June 1st: Chill; attack of hæmoglobinuria.

June 2d: Arrived in Limon 2 P.M. T. 103.5°. Bowels open. Patient vomiting and unconscious, jaundiced. Urine black and thick. ℞ Antikamnia gr. iv. Calomel gr. iv., statim. ℞ Acid hydrobromate of quinine gr. xxx., to be given before 8 P.M. in enemata and suppositories. Hot applications to loins. Tincture iodine (fort.) applied to liver and spleen. Eight P.M., T. 100.5°. Patient still unconscious. Valentine's meat juice (peptonized) given by rectum.

June 3d: 8 A.M., T. 101°. Patient regained consciousness. ℞ Antikamnia gr. iv., with whiskey and water. Suppositories of quinine continued. Saline purge given. Acid hydrobromate of quinine gr. xv., given by mouth. Applications to loins, etc., continued. Eight P.M., urine clearer. T. 100°.



Case II.

June 4th, 5th, 6th: Patient continued to improve. Temperature normal. Urine clear.

June 7th: Relapse. T. 101.5° F. Same treatment. Urine black; blood in urine for thirty-six hours.

June 8th, 9th, 10th, 11th, 12th: Patient gaining strength; no fever. ℞ Quininæ sulph. gr. xx., given

per day from 7th to 12th. ℞ Ferri et pot. tart. gr. iiss., aquam ad ℥ ss. Sig. Every four hours.

June 13th: Chill, fever; T. 110°. Hæmoglobinuria in forenoon, disappearance of fever and blood by evening. ℞ Quinine, gr. xxv., given daily until the evening of June 18th.

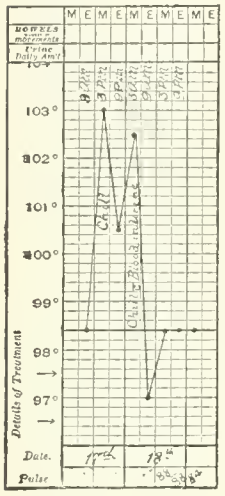
June 19th: Gr. xl. given. Temperature normal from June 13th to 19th.

June 19th: Slight rise of fever. No hæmoglobinuria.

Temperature chart by Mr. George Charles Coles, M.R.C.S.

Case III.—H. C. B——, white, American, aged thirty-two years. Hæmoglobinuria with intermittent fever.

Past history: Prolonged residence on coast of different parts of Central America, resulting in chronic malaria with well-marked malarial cachexia and greatly enlarged spleen and liver; last malarial attack July 1st to 3d.



Case III.

Present history: Intermittent fever with chill at 3 A.M. and 3 P.M. every day.

July 17: 9 A.M., temperature normal. Three P.M., chill, T. 103°. Quinine gr. xl., taken by patient in 2-gr. pills. Nine P.M., T. 100.6. Patient has taken no other medicine.

July 18th: 3 A.M., chill with T. 102.5°; P. 114; attack of hæmoglobinuria. ℞ Antikamnia gr. xv. Sig. stat. cum whiskey and water. ℞ Calomelanos gr. x., pulv. jalapæ gr. viii., pulv. rhei gr. viii. M. Mitte in iii. wafers. Sig. One every hour. Hot fomentations to loins; regions of liver and spleen blistered. Meat juice given. Nine A.M., T. 97°. ℞ Quinine gr. i. in wafer. Mitte iii. Sig. One at 10 A.M., 11 A.M., 12 M. ℞ Ferri et pot. tart. gr. v. ,liq. arsenicalis ♏ iv., aquam ad ℥ i. Sig. Every three hours. Three P.M., no chill; T. normal; P. 88. Urine less dark. Nine P.M., urine clearer. T. normal; P. 88.

July 19th: 9 A.M., T. normal, P. 84. Urine clear, no blood, no albumin. ℞ Quin. acid. hydrobrom. gr. x. Ft. pulv. Mitte tales iv. Sig. One at 10 A.M., 11 A.M., 12 M., 1 P.M. (this salt given on account of irritability of the stomach). Three P.M.: Patient's temperature normal, pulse normal. No return of fever. Further treatment: Quinine gr. xxx. per diem; iron and arsenic tonic; occasional dose of podophyllin. No relapse in six months.

Temperature chart by Mr. George Charles Coles, M.R.C.S.

Not to enter at too great a length on these cases, I will just mention in brief the treatment I adopt, more or less modified, in all cases of malarial hæmoglobinuria. During a chill, if the patient has a high temperature and hæmoglobinuria, I have the patient put into blankets with hot-water bottles, and give antikamnia with caffeine and brandy. Generally in fifteen or thirty minutes, or even less, the patient begins to sweat; his pain is less, and he is every way more comfortable.

Purgative: I give a purgative, generally calomel, sometimes assisted by podophyllin and always followed by phosphate of soda. I give quinine as soon as possible, and if the patient cannot retain it on his stomach I give it by hypodermic injection, using all antiseptic precautions. The solution I generally use is a twenty-five-per-cent. solution of acid hydrobromate of quinine. At the same time as this treatment is carried on I have hot applications applied to the loins, and mustard plasters or blisters, or tincture of iodine (fort.), applied to the liver and spleen, which latter is always tender and enlarged.

Iron and arsenic: As soon as the patient's stomach is in better condition I give iron combined with arsenic, and when he is convalescent I add iodide of ammonium, and order inunctions of red iodide of mercury ointment to the enlarged spleen and liver.

Diuretics: After the hæmoglobinuria has disappeared, if there is any albuminuria at all, I give saline diuretics to flush out the kidneys.

The conclusions I draw from my experience are: (1) Quinine causes irritability of the kidneys and may cause hæmoglobinuria. (2) Malarial attacks in chronic cases with malarial cachexia may cause hæmoglobinuria. (3) In these cases quinine has lost much of its specific effect, and large doses must be exhibited. Should there be a periodicity, we must give the quinine before the time of attack. (4) The action of quinine must be assisted by such drugs as iron and arsenic, and, more important even than quinine, the liver must be acted on well, and the effect kept up. I have never been able to cure an attack of hæmoglobinuria without getting the liver active; the bilious vomiting in these cases sufficiently indicates the necessity of this.

## CONCEALED MENSTRUATION.

By A. BROTHERS, B.S., M.D.,

NEW YORK.

ADJUNCT PROFESSOR OF GYNÆCOLOGY AT THE POST-GRADUATE SCHOOL; VISITING GYNÆCOLOGIST TO BETH ISRAEL HOSPITAL, ETC.

The subject of normal menstruation is a very large one. Nearly all of the older and most modern textbooks discuss it somewhat in the following manner. During the maturation and discharge of a Graafian follicle a stimulus is sent, once in twenty-eight days, to the uterine mucosa, which results in the expulsion, during a number of days, of effused blood, epithelial cells, granular débris, and mucus. Menstruation is thus made to be absolutely dependent upon ovulation and can be interrupted only by pregnancy and lactation. Unfortunately for this simple explanation, which makes ovulation the initial act in the generative cycle, it is known that ovulation, independently of menstruation, antedates birth, extends into extreme senility, and frequently (particularly during lactation) occurs irrespective of the monthly flow (L. Tait, Byford, Kirkes' "Physiology," etc.).

It would seem that the relationship could be immediately and absolutely determined by removing the ovaries. As a matter of fact, in the majority of women, after double oöphorectomy menstruation does come to a sudden and complete stop. But how shall we explain that small proportion of cases (one per cent., Sänger; twelve per cent., Glaenecke) in which the menstrual flow persists? In this country and on the continent operators above suspicion—Tuttle, Lee, Bantock, and others—have reported such instances. Mundé, Sänger, and others would have us believe that the diseased uterus was left. Coe and the German school tell us that a recurring pelvic congestion readily accounts for the persistent menstruation; and still others (including Howard Kelly) inform us that these operations were incomplete, resulting in the inadvertent presence of ovarian tissue.

Lawson Tait for many years maintained a theory of his own. He claimed that "the influence of the Fallopian tubes in being at least the starting-point of the phenomena of menstruation is shown (*a*) by the almost constant symptom of precedent pain in case of occlusion of the tubes; and (*b*) by the appearance of the

menstrual discharge in the clamp cicatrix before its appearance from the uterus." One of the strongest opponents of this theory is Pozzi, who says that "removal of the Fallopian tubes does not seem to influence menstruation, providing that the ovaries be healthy."

In recent literature we find a number of instances apparently sustaining Tait's theory. Thus H. Thomson adds two cases to three already on record. In the first of these cases a tubo-abdominal fistula, resulting from a pyosalpinx, was observed to discharge menstrual blood at each monthly period. In the second case, eight months after laparotomy for ectopic gestation, a similar discharge from the fistulous tract was noted with each menstrual uterine flow. The fistula could be followed down to the left horn of the uterus. In both cases the bloody fistulous discharge began and ceased at a time corresponding to that of the uterine discharge. This writer calls attention to the observations of Martin and Leopold, during autopsies on women who died while menstruating, according to which the tubal mucous membrane showed appearances analogous to those of the uterine mucosa but to a lesser degree. It has, however, been noted by other observers that in autopsies on menstruating females the tubes often contain no blood even when the uterine cavity may show swelling of the mucosa and be filled with considerable blood (Fuld). Bond has very recently reported his observations on five Fallopian tubes removed during menstruation, in all of which bloody mucus was present. From one of these experiences he concludes that tubal menstruation precedes that of the uterus. Finally, Schroeder and Fritsch regard hæmatosalpinx as due to vicarious tubal menstruation. A closure due to inflammatory causes of both ends of the Fallopian tube, I think, would more readily account for this pathological condition on the theory of physiological tubal menstruation.

From the foregoing it must be conceded that normal menstruation at times may involve the mucous membranes of both tubes and uterus. Even A. P. Dudley's repeated observation that, after laparotomy done during menstruation, free blood is regularly found in Douglas' cul-de-sac—and which he explains by hemorrhages from the surface of the ovaries—may be equally explained on the theory that tubal menstrual blood has escaped through the fimbriated extremities into the peritoneal cavity.

I shall now narrate briefly the history of my case.

On May 30, 1898, Dr. Emil Kober brought to my office Mrs. M. H——, aged thirty-nine years, married thirteen and one-half years. She had given birth to two children, but had no history of miscarriages. During the last pregnancy—which occurred ten years previously—she had a severe fall, as a result of which the child died and ten or twelve days later had to be extracted with forceps.

The menses made their appearance at the age of sixteen years, and recurred at four-weekly intervals up to five months ago, since which time they have completely disappeared. Formerly her menstruation was free from pain, but for a number of years she suffered from dysmenorrhœa.

At present she complains of the following symptom: Once every four weeks she thinks she is going to be unwell. She suffers pelvic cramps of such intensity as to confine her to bed for three days, but, in spite of her suffering, she fails to see a trace of menstrual blood. After the third day she feels perfectly well and suffers no pain during the intervals. As the time for the next period approaches she becomes drowsy. This cycle of events has been recurring with mathematical precision for a period of five months. She shudders at the prospect of the next attack, and will submit to anything which promises to ward it off. She dates the first deviation from her normal health to the accident of ten years ago, when, from the violence of the fall, she lost consciousness for almost an hour. As before stated, although labor pains immediately set in, she had to be delivered artificially ten days later. Excepting a varicose ulcer of the leg her previous history is good. Her mother died of heart disease at the age of forty-eight years. Within the past year she has lost very much in weight—some forty-four pounds. Her bowels move regularly. Her appetite and sleep are good. She passes water too often.

On examination I found the uterus anteflexed and pushed forward by a cystic tumor of considerable size in Douglas' cul-de-sac. Because of abdominal rigidity and tenderness it was not possible definitely to map out the parts, but the indication for operation was clear, and I referred the patient to the Post-Graduate Hospital.

On June 4th, under ether anæsthesia, a large bulging cystic tumor was felt behind the uterus. The posterior vaginal vault was incised and the cyst punctured, when a large quantity—possible six or eight ounces—of dark, tarry, unclotted blood escaped. A careful examination by Dr. A. P. Dudley (who happened to be present) and myself revealed extensive adhesions and a second tumor high up on the right side. For these reasons we agreed upon the advisability of packing the vaginal wound with iodoformized gauze and attacking the tumors from above. With the patient in the Trendelenburg position I made a large abdominal incision and proceeded to separate the right-sided tumor from its numerous adhesions. During this manipulation the thin-walled and distended sac burst at one point, allowing about a half-pint of the same tarry liquid to escape into the peritoneal cavity. Hastily lowering the patient, both tumors were separated from their adhesions and removed. The peritoneal cavity was washed out with a pitcherful of sterilized water, and the abdominal wound entirely closed.

For a number of days after the operation there was no rise of temperature. Then the patient developed fever, which was traced to an acute nephritis with left-sided pleuro-pneumonia. After about two weeks the symptoms improved, and at the end of four weeks she was discharged cured. She has remained well down to the present time, eight months later.

The tumors, artificially distended with cotton and considerably smaller than they were previous to rupture, measure respectively 2 × 3 and 2 × 2 inches. Both specimens consist of ovarian sacs in which the parenchyma is entirely absent. Each one communicates by an artificial opening with the corresponding Fallopian tube. The openings at the fimbriated extremities are completely obliterated. The tubes are not particularly increased in size, but at their outer ends seem to be flattened and agglutinated to the walls of the ovarian sacs

My original explanation of the specimens was the following: For some unknown reason, in a woman at the change of life, tubal menstruation had persisted, and the tubes being shut off, for pathological reasons, from the uterine and peritoneal cavities, had discharged themselves, after agglutination and perforation, into the substance of the ovaries.

Unfortunately for this theory, a hæmato-salpinx implies the presence of a tumor, usually sausage-shaped, consisting of a hyperdistended, blood-filled, Fallopian tube. In the cases described by Fritsch and Stephan Fuld (who has made the most careful study of the subject) such a tumor was invariably present. This led me to adopt the view of Dr. A. P. Dudley, who saw the specimens in their fresh state, that we were dealing with a case of primary menstruation into the ovaries. Why the seat of the hemorrhage should have

been in the ovaries is not so easy to explain. Still it is known that occasionally, at the time of the menopause, vicarious menstruation may occur ("American System of Gynæcology"); and, on this theory, I can imagine that such bleeding may take place into the ovaries as well as from the nose, rectum, or other portions of the body.

One more condition deserves a moment's attention. It is well known that an ovarian blood-tumor may result from the twisting of the pedicle of a previously existing ovarian cyst. Such a torsion of the tumor pedicle usually results in interstitial hemorrhages leading to a sudden increase in the size of the organ and destruction of the parenchyma Every operator of experience has met these cases Last year I presented such a blood-filled tumor before the Medical Society of the Deutsche Poliklinik. This condition, however, is apt to be unilateral; torsion of the pedicle is present, thick clots are mixed with the sanguineous liquid. In our case the tumors were bilateral, there was no twisting of the pedicles, and the blood was distinctly free from clots. Besides, there was the history of five recurring menstrual cycles at regular, four-weekly intervals. For these reasons I am led to believe that this was a rare case of concealed (vicarious?) menstruation.

In conclusion, though distantly connected with the subject under consideration, it may be of interest to note that Fuld has collected sixty-five cases of hæmatosalpinx (associated with atresiæ of the genital tract) in which there were no less than forty-eight deaths. With such a startling mortality the propriety of surgical intervention, in cases in which retained menstrual blood hyperdistends the tubes or ovaries, will readily be conceded.

## CUTANEOUS ELECTROLYSIS.

By FRED J. LEVISEUR, M.D.,

NEW YORK.

Cutaneous electrolysis has not become the property of the general practitioner for two reasons: First, because the indications for the use of electrolysis are not yet very clearly understood, and secondly, the instrumentarium is not simple enough. These operations when performed with instruments attached to the positive pole of a galvanic battery have little practical value; but when the fine needle is connected with the negative pole they should become much more popular with physicians.

When a needle connected with the negative pole is thrust into the skin and the current closed, caustic alkali is quickly developed around the needle; interrupt the current and this development ceases. This caustic effect varies according to the closeness of contact with the different layers and according to their structure. The area of cauterized tissue may be said to represent a cone with its base at the point of the needle and its apex at the epidermis. Changing the position of the needle causes a larger quantity of tissue to be destroyed from one single point of epidermal opening. This explains why so little scarring follows the operation, and also why infection from the outside is so rare afterward. It is easily controlled as regards its local effects, and gives more favorable cosmetical results; these advantages make it superior to other agents used for purposes for which electrolysis is indicated.

The instrumentarium consists of a galvanic battery, a rheostat, a milliamperemeter, a pair of cords, a sponge electrode, a needle-holder, and a needle. The details of the construction of the needle-holder are important only in one respect: that is, the possibility of carrying the needle at an angle so that it can be handled like a pen. A sewing-needle of the very finest size should be used with the holder. Some years ago the speaker devised a sponge electrode for connection with the positive pole, by which the patient could close and interrupt the current by merely opening or closing the hand, and made it possible for the patient to modify the strength somewhat.

For the removal of superfluous hairs a good forceps is required, preferably one which is square and not pointed at the end.

Electrolytic operations are quite painful because of the electrolytic action itself; therefore, to avoid much pain, the patient should be instructed not to touch the sponge until the needle has been introduced: in this way the patient will avoid an unexpected shock or sudden pain, and will be enabled, to a certain degree, to control the intensity of the latter by either compressing or releasing the sponge. Nearly all the salves or lotions recommended to make electrolytic operations painless are more or less unreliable. Freezing the field of operation with methyl-chloride spray (kelene) is the only thing to be considered.

When subjecting the normal skin or solid tumors to the action of electrolysis, after a few applications it will be found that there is formed a certain anæsthetic area. The small point around the end of the inserted needle becomes white. A good plan is to insert the needle in a number of hair follicles situated in the area rendered anæsthetic by the freezing, and leave it in each follicle about five seconds. After the skin has returned to its normal condition, all these follicles will be sufficiently blunted as regards sensitiveness to permit the introduction again of the needle with very little pain. Wheals the size of a pea or larger should not occur, as they are a sure sign that the superficial layer of the epidermis has borne the brunt of the action and the deeper parts of the hair follicle have escaped destruction. Foaming is, in the great majority of cases, a favorable sign as regards success. One should never leave a destroyed hair in place; the slightest traction of the forceps should be sufficient to remove the same.

The percentage of returning hairs varies according to the precision and care with which the operation is performed. Patients with well-developed panniculus adiposus are especially well adapted for the operation, and only a minimum of the hairs will return. Thin persons with an inelastic skin are not good subjects. To treat and cure a case of general hirsuties requires many sittings and greatly taxes the patience of the physician and the patient. The removal of hairs growing on pigmented moles requires a longer application and a stronger current than for hairs growing on the normal soil. The mole should be destroyed simultaneously.

Excellent results follow, as a rule, the electrolytic treatment of nævi pigmentosi associated with hypertrophy of all cutaneous structures. The nævus verrucosus is quite easily removed by transfixing it at its base until it has become blanched. The nævus papillomatosus is destroyed piecemeal in a number of sittings. The smooth nævi require a little more care.

Electrolysis is a superior remedy for the removal of so-called soft warts, verrucæ carneæ. The sooner they are removed the better for the patient, and electrolysis is a most effective remedy and one that should be used energetically and promptly. Hard warts are first thoroughly moistened with a two-per-cent. solution of salt before the needle is carried down through their base. In about five to ten minutes the wart blanches, then becomes mummified, and drops off after one or two weeks. I have repeatedly and successfully destroyed xanthoma near the eyelid with the electrolytic current.

Nothing less than complete destruction of the xanthomatous deposit will be followed by good results, consequently, white scars are unavoidable. Methyl chloride cannot be applied near the eye, but a minute quantity of pure carbolic acid will produce a sufficient anæsthetization to make the operation bearable.

Following in the lead of Hardaway, of St. Louis, and Brocq, of Paris, I have treated four cases of true keloid by electrolysis. Two of the cases were in dispensary patients who disappeared from observation shortly after treatment was commenced. The other two were in private patients and were watched carefully. In one of these cases the keloid measured three inches in length and one and one-quarter inches at its broadest point, it projected about one-quarter of an inch. Fifty sittings, in half-weekly to weekly intervals, had little effect, and treatment was abandoned. The other case was that of a young man whose keloid had been thoroughly excised but promptly returned. I succeeded in flattening the tumor considerably, it was only a moderate success.

A case of dermatitis papillaris capillitii, or acne keloid, began to spread when treated with the thermocautery, but I was able to stop its progress and produce improvement after six sittings and finally effected a cure.

Regarding the electrolytic treatment of angiomata, the indications should be very accurately defined. Two varieties are distinguished, the angioma plexiforme (simple angioma, telangiectasis) and angioma cavernosum. On the border line between the two the nævus vasculosus or vascularis ("port-wine mark") finds a place. The seat of predilection for plexiform angioma is the forehead and more particularly the region of the orbita (embryonic fissures). If the spots are entirely on the level with the surrounding skin and occupy the upper and lower eyelids, they should be left alone; also when they occupy the seat of the eyebrows. The vascular moles, which are somewhat elevated above the skin, can be more easily removed by electrolysis. The best results are obtained when the spots are small and stationary: treatment begun then prevents the spreading of the moles in later years. The cavernous angiomata are oftener seen in adults, grow slowly, and are frequently found near mucous membranes. For deep-seated ones, the knife should be used. For angiomata cavernosa situated on the body, a surgical operation is certainly preferable to electrolysis; but, if the knife cannot be used, then this procedure offers the best remedial agent at our disposal.

Angioma serpiginosum of Hutchinson and angiokeratoma are reported to have been treated successfully by electrolysis. In the treatment of lupus erythematosus, one of the most difficult problems of dermatological therapeutics, electrolysis has found a permanent place. The best time to interfere is at the very first appearance of the cutaneous lesion, even the small doubtful spots being removed at once before the disease has clearly manifested itself.

In cutaneous affections of more or less malignancy electrolysis cannot compete with the knife. It should not stand in the way of surgical intervention. This refers especially to epithelioma.

In closing I would emphasize the fact that electrolysis performed with a needle attached to the negative pole is not simple cauterization. It may be compared to a most accurate and equally distributed injection of a caustic solution into the tissues.

**Mercurial Poisoning.**—Subcutaneous injection of physiological salt solution and energetic massage.—*Riforma Medica*, No. 38, 1899.

## FACIAL ERUPTIONS DUE TO INTRANASAL DISEASE.[1]

BY CARL SEILER, M.D.

SCRANTON, PA.

In a recent number of the MEDICAL RECORD a paper appeared on facial eruption, upon which I commented by suggesting that nerve reflex was not the only cause of this unsightly and distressing affliction so common in adolescents, especially young women.

When we look into the anatomy of the parts and their physiological relation to each other, and weigh one effect or cause against another, we shall find that pressure upon the capillary circulation within the nose, as well as pressure upon the cavernous tissue of the turbinates, has much to do with the disturbances of the capillary circulation of the skin of the face and nose.

For instance, we are all aware of the fact that chronic alcoholism will produce hyperæmia of, and consequently pressure in, the internal nasal structures, and a result is the so-called "rum nose"; we also know perfectly well that sexual excess or suppression of sexual desire in adolescents will have its influence upon the circulation of the capillaries of the face so as frequently to produce acne punctata. This latter is, according to Fox, Bulkley, Hebra, and other eminent dermatologists, caused by a hyperæmia of the sebaceous glands, resulting in an increased amount of sebaceous secretion and, the outlet of the gland itself being obstructed by dust or other foreign matter, a distention of the lining wall of the gland is caused, which then, by the retrograde metamorphosis of the sebaceous material into fatty and finally caseous substance, produces comedones. Auspitz frequently observed acne punctata follow variola and diseases of infancy. Thin mentions cases of the hemorrhagic form of the disease; while Hebra makes a number of subdivisions, which, however, are purely topographical and in no way conflict with the generally accepted division, namely, acne punctata and acne rosacea.

The so-called blackheads, to use the popular term, are nothing more than the accumulation of dust and dirt in the external openings of the excretory ducts of these glands, which, having been distended to an abnormal size, become visible to the naked eye. It is, however, also well known that nervous influences, whether central or peripheral or reflex, will produce an increase of circulation in, and dilatation of, the capillaries of the skin of the face, as pointed out before; as in the blush of shame. Close observers of physiological and pathological phenomena also concur in their opinion that ingestion of hot and stimulating foods or drinks, such as hot soups, coffee, hot Scotch, etc., will temporarily produce an increase of temperature in the capillary circulation of the skin and particularly the skin of the upper portion of the body. Hence comes the common notion of the laity that a hot whiskey punch makes one feel warmer after a cold ride, while, on the contrary, all close clinical observers know that alcohol will reduce body temperature. Consequently, any increase of the flow of blood in the capillaries of the integument of the face, when kept up by internal or external pressure or by reflex irritation of the vasomotor nervous system, must necessarily interfere more or less with the normal actions of the various glands of the skin, racemose or otherwise, and by so doing their function, which is that of anointing the skin and keeping it in a normal condition, is interfered with.

There is no organ, no matter how minute, no matter how large, whether visible to the naked eye or only through the microscope, that has not its particular function, which, when interfered with by any cause

[1] Read before the Scranton Clinical and Pathological Society, June 2, 1899.

whatsoever, will not produce a disturbance in the general organism, either within its immediate neighborhood or remotely through the channels of the nervous, vasomotor, or lacteal systems, in a greater or less degree. Take, for instance, the painful symptoms caused by the migration of trichinæ in the tissues.

Now if such microscopic worms are capable of producing general pain and discomfort, as well as inflammation of adjacent parts, why is it not rational to suppose that a turgescence of the erectile tissue of the lower or middle turbinated bones, pressing upon the capillaries of the septal mucous membrane of the nose, may not produce disturbances of the circulation of the skin of the face?

There are two or rather three different commonly recognized facial eruptions, leaving out the topographical distinctions: Acne punctata, the most common of all, the causation of which has already been indicated, acne rosacea, and lichen ruber, or, what is still more uncommon, and according to Hebra and v. During occurs only among Germans or those of German descent, lichen planus.

My observations for a number of years, ever since the introduction of cocaine as a local anæsthetic into nasal surgery and its unfortunate application by the laity for the temporary relief of nasal obstruction, show that these facial eruptions have become so common as to attract the attention of rhinologists. My own experience in a large number of cases has shown that the pressure of the cotton plugs, and the contraction produced by the cocaine of the capillaries of the nasal mucous membrane, will excite a corresponding hyperæmia of the capillaries of the facial integument.

Many of these points I previously brought out in a paper read before the County Medical Society of Philadelphia, in the fall of 1887, and I can add in this paper only such new facts as have presented themselves to my observation since: particularly that acne rosacea is more commonly observed in connection with the atrophic form of nasal catarrh and is not nearly so frequent in the hypertrophic variety of the disease as acne punctata.

Still the subject is one deserving the closest attention of every practitioner, and I therefore have taken the privilege of bringing it to the attention of all of you.

As to treatment, my above remarks will indicate the means to be adopted for the relief of the sufferer, but the physician should not forget that every case is to be examined in detail and then treated according to the indications revealed by a careful investigation as to the near or remote causes of the trouble.

In the first place, the patient should be advised not to use hot water in washing the face, but to use cold water and castile soap in the process. Next, all local or remote causes, whether reflex through the nervous system or caused by merely local pressure upon the vascular system, should be removed. Unctuous applications should never be employed, as they have a tendency still further to obstruct the outlets of the sebaceous glands.

---

**Effects of Foreign Bodies in the Bronchi.**—Dr. R. Sevestre (*British Medical Journal*, January 21st) concludes an article on this subject as follows: "The effects of foreign bodies in the bronchi I have divided into two stages. In the first stage the most noticeable feature is the collapse of the lung, in the second stage the inflammatory changes predominate. Of these, the most important are changes in the bronchial tubes, their dilatation with walls thickened and full of secretion, the consolidation of the lung, and it may be its final disintegration, and the changes in the pleura, in some cases the formation of an abscess."

## PERSONAL OBSERVATION ON AN UNUSUAL CASE OF LABOR.[1]

By P. T. O'CONNOR, M.D.,

WATERBURY, CONN.

On October 28, 1898, at 5 P.M., I saw for the first time Mrs. S——, a well-developed young woman, aged twenty-five years. She complained of having had severe irregular abdominal pains since early in the morning, and wanted to know if she was about to be confined. According to her own reckoning she did not expect her confinement would take place until some time between November 10 and 15, 1898. After inquiring into her previous history, character of the pains, etc., I informed her that she had all the presumptive signs and symptoms of an approaching labor, and that an examination would be necessary in order to make a positive diagnosis.

The woman was placed in position, and after the usual preparation I attempted with the index finger of my right hand to make a vaginal examination, but, to my surprise, was unable to do so. After making several unsuccessful efforts to find the vagina, I began to doubt whether I had a case of labor to deal with. The results of external palpation, together with the contour of the abdomen, were quite indicative of a case of pregnancy. With the stethoscope over the lower abdomen the fœtal heart could be heard. The woman was placed crosswise, the hips were brought forward well over the edge of the bed, and after separating the labia I noticed a distinct membrane which almost completely occluded the vagina. In the centre of this membrane there was an aperture about one-quarter of an inch in diameter, large enough to admit the tip of my little finger, which was forced through and withdrawn. The ring finger was then forced through and withdrawn, and finally the index finger was introduced.

With the index finger in the vagina, it was quite easy to make out a distinct membrane which was quite lax, about one-sixteenth of an inch in thickness, and at the vaginal portion there was a well-defined circumscribed ring. I then determined to note the condition of the cervix, which was sufficiently dilated to admit the index finger. A vertex presentation was then made out, occiput anterior and to the left.

I informed the woman that her labor had already begun, and also explained the abnormal condition of her case. A consultation was suggested, and Dr. F. E. Castle was called in. He saw the patient at 6 and at 9 P.M. The membrane, or hymen, was ruptured by manual dilatation with the fingers. At first we thought it would be necessary to incise the ring, in or at the posterior portion of the vagina, in order to accomplish the delivery of the child. But on reconsidering the matter, it appeared to us that the expulsive forces acting from above would have a tendency to force the presenting head in the direction of the least resistance, and that the incision might serve as a starting-point for a laceration into the rectum. Therefore we decided to take a more conservative view of the case, and trust to nature until it seemed inevitable to make the necessary incision.

We waited until 2 A.M., by which time the advancing head was well down on the pelvic floor. The fibrous ring offered considerable resistance to complete stretching of the perineum. The pains were diminishing in force, and it seemed necessary, in the interests of both mother and child, to hasten delivery. We applied the forceps, imitating nature as best we could. After a prolonged effort, it was possible with two fingers of the right hand introduced into the rec-

[1] Read before the Waterbury Medical Society, December 12, 1898.

tum to catch the chin; with three fingers of the left hand on the occiput the head was held firmly while the instrument was being removed. We exercised every precaution to preserve the perineum during the delivery of the head, and assumed that we were successful in our efforts. But after the child was born we discovered that the ring had ruptured and with it the perineum and vagina. After waiting the usual length of time for the placenta to come away, the Credé method was applied to the fundus of the uterus, and with gentle traction on the cord it was impossible to expel the placenta. The cord was followed upward into the lower uterine segment. Above the latter there was a constriction, and through the stricture the cord continued. It was then apparent that we had a case of adherent placenta and "hour-glass contraction" to deal with.

Following the technique of asepsis, the hands and forearms were prepared. The right hand was introduced into the vagina to the point of constriction. Then, by pressing the uterus downward, the index and middle fingers with the whole hand forced through the constriction, the adherent placenta was removed. The lacerations were immediately sutured, and union by primary intention was the result. No irrigation whatever was used, knowing that we were aseptic in our work; therefore the application of antiseptics was not indicated. The woman made an uneventful recovery. The temperature and pulse remained normal during the confinement. It is interesting to note that a living child, male, weight twelve pounds, was successfully delivered after considerable manipulation.

There are two points in this connection which we wish to emphasize, viz., the rarity for conception to take place under the existing conditions already described, and the value of asepsis in general practice. It has been thoroughly demonstrated that in our large hospitals, with trained assistants in every department, with modernly equipped operating-rooms, where glass, marble, and concrete enter almost entirely into the construction, where dust can be reduced to a minimum, and cleanliness is a virtue advanced beyond its usual position and ranking next to godliness, asepticism is possible.

In private practice simplification is the important factor. It was the difficulty of application of the Listerian method that prevented its adoption by the general practitioner. The aseptic method consists of three stages — cleanliness before, during, and after manipulation. Once mastered, the technique soon becomes a matter of routine, and we see no reason why it should not be adopted in ordinary general practice. By referring to the past we see that no sooner was one theory exploded and, like the autumn leaves, fallen into disuse, than new ones were brought to the unguarded interval, and the wild onset was resumed. The foundation of antiseptic midwifery was laid by Semmelweis in Vienna in 1847. Pasteur in 1860 and the next few succeeding years settled the whole question by his masterly review of the field and his own remarkable series of experiments. Following this came Lister's appreciation of the results of these experiments and their application to surgery. Later on bacteriology became an established science, and soon began to cast the rays of its powerful search-light in certain direction and to illumine the valleys of darkness. This, in turn, paved the way for asepticism, which has revolutionized modern surgery.

The work of man will always be open to adverse criticism. Perfection never has been and never can be attained. The advocates of asepsis do not claim for it that by its principles and practice the ideal has been accomplished. They do, however, assert that in certain departments, at least, a direct approach has been made toward perfection, or, in other words, the foundation of the ideal has been laid. The temple may never be completed. But on this foundation will rest the triumphs of future progress.

## Progress of Medical Science.

**Pathogenic Bacteria after Death.** — Ay the investigations of Klein (*Centralblatt für Bakteriologie*, May 31, 1899) it is shown that it is possible to find for a period of twenty-eight days after death cultures of bacillus prodigiosus in the peritoneum of animals buried in the earth or sand; these animals having died from this organism experimentally introduced. After six weeks the cultures were negative. Staphylococcus pyogenes aureus had the same resistance. The vibrio of cholera still gave cultures after nineteen days, but not after twenty-eight. The bacillus typhosus and the bacillus of diphtheria lived from fifteen to twenty days. That of the plague was still alive after seventeen to twenty-one days, but never lived longer than three weeks. It was possible to stain the tubercle bacillus from the organs after three weeks, but no positive cultures could be obtained after that time by inoculation. Hence Koch's bacillus is short-lived after interment.

**Differential Stain for Tubercle Bacillus.**—In the *Centralblatt für Bakteriologie*, May 31, 1899, Marzinowsky describes a method, designated new, of differentiating the bacilli of tubercle, human and of birds, leprosy, and of the smegma. He uses the carbol fuchsin (two parts of water to one part of stain) and Loeffler's alkaline methylene blue. The smear is placed in the fuchsin for three or four minutes and then in the methylene blue for from two to three minutes, after washing between stains. Human tubercle is stained by this process only after a long immersion in the fuchsin; bird tubercle stains quite readily; the bacillus of leprosy takes up the red stain easily, and is readily decolorized by alcohol or after ten minutes by the methylene blue. The smegma bacillus stains blue after ten to fifteen minutes.

**Meat Poisoning due to Proteus Vulgaris.**—Glucksmann (*Centralblatt für Bakteriologie*, May 20, 1899) reports a case of poisoning from ham. The clinical picture was that of severe gastro-enteritis followed by fatal collapse. The autopsy showed the lesions of gastro-enteritis, and a bacteriological examination of the cadaver, made too late after death for exact conclusions, showed the presence of colon bacillus in the blood, and pyogenes aureus, proteus, and colon bacillus in the intestines. The bacteriological examination of the meat, however, showed the presence of a long bacillus having the growth, characters, and staining reactions of proteus vulgaris. Experimental inoculation in mice and guinea-pigs with this organism resulted in similar lesions, and death with isolation of the organism in some of the cases. It seems certain that the process of smoking the meat causes the sterilization of the superficial layers only, and that underneath there is left an excellent culture-ground for bacteria to develop. These cases are daily assuming an increasing medico-legal importance.

**Chemotactic Action of Toxins on Leucocytes.**—Bohland (*Centralblatt fur innere Medicin*, April 29, 1899) has studied the actions of the toxins of typhoid and of colon organisms on leucocytosis. It has been demonstrated that there is a diminution of leucocytes in typhoid. This hypoleucocytosis usually lasts as long as the fever. Bohland and Steinhaus made the

following observations on rabbits. The toxins were injected after a twelve hours' fast, the norm of blood counts having been established. The blood was counted ten, twenty, thirty, and sixty minutes after the injection of the toxins. In eight of the ten experiments there was found for the typhoid toxin a diminution in the leucocytes after ten to fifteen minutes, which diminution reached its maximum after twenty to thirty minutes. In one of the other experiments there was no hypoleucocytosis by reason of the small amounts of toxin used, and in the other a decrease was noted after a temporary increase. Hence the toxins of typhoid have negative chemotactic properties. In eleven similar experiments made with the colon bacillus there was a hyperleucocytosis varying from twelve to seventy-four per cent. Hence there is a positive chemotaxis in the toxin of this organism. Nine experiments made with the blood serum of typhoid-fever cases showed a marked negative chemotactic action. This method is suggested as a differential means for identifying these two organisms.

**Paralysis Agitans.**—The drugs which are in use for paralysis agitans, and from which some benefit in dissipating symptoms and fulfilling indications may be expected, are hyoscyamus and duboisine, Indian hemp, opium, hæmatogenous agents such as arsenic and iron, and occasionally gelsemium and veratrum viride. Of these, the most important by far are the first mentioned. Given hypodermatically, which is the preferable way when possible, or by the mouth, they promptly mitigate the severity of the tremor, and have a pronounced tendency to relax muscular rigidity. They are both powerful toxic agents, and must, therefore, be given with care.—*New York Medical Journal*, July 8, 1899.

**The Aural Complications of Measles.**—From a study of the literature and from personal experience, Heymann (*Deutsches Archiv fur klinische Medicin*, Bd. 63, Hft. 3 and 4) is led to conclude that disease of the ear is a regular complication of measles, that under unfavorable conditions and incompetent treatment may, and often does, constitute a serious menace to the development or even the life of the patient. As, in the majority of instances, the unpleasant results can be averted by intelligent treatment, it is important to pay especial attention to the auditory apparatus in all cases of measles.

**The Effect of Baths, Massage, and Exercise on the Blood-Pressure.**—As the result of an experimental inquiry, Edgecombe and Bain (*Lancet*, June 10, 1899) conclude that cold baths allay the arterial pressures, maximum and mean, and lower the venous pressure. After reaction the arterial pressure falls and the venous pressure rises. Percussion, added to cold, increases the rise in arterial pressure. Warm baths of plain water lower the arterial pressures, and both absolutely and relatively lower the venous pressure. Turkish baths lower the arterial and venous pressures to a greater extent, though the fall in venous pressure is proportionately not so great as that in arterial pressure. Saline baths at warm temperatures lower the arterial pressures to a greater extent than plain water baths at the same temperatures. The venous pressure, though absolutely lowered, is relatively raised. When the amount of saline material is considerable, a further lowering of arterial pressure takes place, while the venous pressure becomes absolutely raised. Dry massage lowers the arterial pressures, and relatively or absolutely raises the venous pressure, provided the abdomen be not massaged too vigorously. When this is done, a rise in all pressures occurs. Warm temperature, plus massage, has a more powerful effect in the same direction than dry massage alone. The effect of exercise on the blood-pressure depends upon the severity of exertion. In all forms an initial rise in arterial pressure occurs. If the exercise is mild, a fall occurs during its continuance; if severe, the rise is maintained. After exercise, moderate or severe, a fall takes place. The venous pressure is raised during all forms of exercise, and remains raised during the subsequent arterial fall. The return to normal after exercise takes place more or less rapidly according to the gentleness or severity of the exercise and the temperature of the atmosphere.

**Partial Transverse Section of the Spinal Cord.**—Schäfer has been carrying on some interesting and important investigations on the functions of the spinal tracts, which he presents in a preliminary note (*Journal of Physiology*, vol. 24, 1899.) Most of the investigations were carried on on the monkey, a few on the cat. His physiological results following hemisection of the cord agree mainly with those of Mott made in 1892. He found that in the first few days there was complete motor paralysis of all parts supplied with nerves below the section. The limb or limbs on the paralyzed side were swollen and warm (vasomotor paralysis and lessened outflow of lymph) and the skin dry (diminution of sweat). The knee-jerk was exaggerated. Sensation was not lost on the same side as the lesion, but at times appeared dulled. After a few days, unmistakable signs appeared of feeling and localizing even a slight touch, and this long before the motor paralysis had passed away. He states that he has seen no sign of paralysis either motor or sensory on the side opposite to the hemisection in any case in which the section had been strictly confined to the one-half of the cord. Sometimes the adjacent posterior column of the other half is injured, and in that event there is impairment of sensation for a time on both sides below the lesion. The motor paralysis, at first complete, becomes incomplete and finally is difficult to determine. But purely voluntary movements are not recovered or but very imperfectly, although all the ordinary associated movements of the limbs are recovered. After three or four weeks it is difficult to detect any sort of paralysis, but the limb which has been paralyzed is thinner than the other. If the hemisection is made above the level of the eighth cervical nerves, the pupil on the same side is relatively contracted and so remains. The dilator fibres and the pilomotor fibres in the cervical sympathetic do not degenerate but remain excitable. The pupil reacts to light and shade in spite of its being persistently smaller than the other. Excitation of the motor cortex of the opposite cerebral hemisphere produces as a rule no movements in the limbs which have been paralyzed, even if the associated movements have long returned. Lesions of the cerebellar tracts, either of the dorsal alone or with the ventral tract, did not produce any obvious symptoms. Sensation and motion seem unimpaired and the pupil is unaffected. Even when some of the fibres of the pyramidal tract are involved in the lesion, no obvious symptoms are noticeable. The histological results in the light of modern methods of interpretation of degenerative processes are of great interest. He shows that after hemisection the cells of Clarke's vesicular column below the lesion undergo chromatolysis, and eventually (two or three months) almost completely atrophy. The atrophy of these cells is equally complete if the lesion is confined to the dorsal and ventral cerebellar tracts. The atrophy of Clarke's column is less complete if the section is confined to the dorsal cerebellar tract; probably also if it is confined to the ventral cerebellar tract, though the author was not able to prove this experimentally. No other cell groups below the lesion show atrophic changes. It is therefore to be inferred

that Clarke's column gives origin not only to the dorsal cerebellar tract (tract of Flechsig) as shown by Mott, but also to the ventral cerebellar tract (column of Gowers). Clarke's column has also an important relationship to the fibres of the pyramidal tract. After lesions involving these fibres degenerated fibres are seen in large numbers passing from the pyramidal tract toward Clarke's column. No degenerated fibres are traceable from the pyramidal tract into the anterior horns or into any part of the gray matter other than the base of the posterior horns and Clarke's columns. In a further communication to the society (*Journal of Physiology*, vol 24, 1899), Schafer states that the descending antero-lateral tract (tract of Lowenthal) passes its fibres into the anterior horns, and apparently, for the most part, they end by arborizations about these cells.

**The Surgery of the Lungs.**—From a study of two cases of pulmonary gangrene, two of pulmonary abscess, one of pulmonary cavity, one of bronchiectasis, and one of subdiaphragmatic abscess treated by surgical measures, Sapiejko (*Revue de Chirurgie*, July 10, 1899) concludes that incision of the pleura, of the lung, and even of the diaphragm, in cases of subdiaphragmatic abscess, may lead to a favorable issue if pleural adhesions exist; and these are present in the majority of cases in which suppurative processes occur in the lungs. It is of the highest importance to determine the exact situation of the pleural adhesions, through which the way toward the focus of disease is shortest and least dangerous. This may be done by introducing through a small incision in the skin a dull, hollow, fine-shaped needle, connected with a glass tube bent twice on itself and filled with sterilized physiological salt solution. In the absence of adhesions the negative pressure in the pleural cavity will cause the fluid in the tube to move toward the chest, and in their presence the fluid will recede. In the former event the formation of adhesions can be superinduced by injecting concentrated solutions of silver nitrate, formalin, potassic hydrate, etc. The lung may be incised with an ordinary bistoury, and the resulting hemorrhage is usually controlled by packing.

**Tuberculosis in Childhood.**—As the result of a study of seventy-five fatal cases of tuberculosis in children, together with a consideration of the conclusions reached by Northrup from a previous study of one hundred and twenty-five cases of similar character, Bovaird (*New York Medical Journal*, July 1, 1899) finds that the primary lesion of tuberculosis in children is regularly in the bronchial lymph-nodes or the lungs. The early manifestations of tuberculosis in children are extremely indefinite and uncertain. Tuberculous infection of the bronchial lymph-nodes cannot, as a rule, be diagnosticated. Latent tuberculosis is often roused and disseminated by the invasion of another disease (infection), such as measles, diphtheria, etc., the presence of tuberculosis not having been previously suspected. The common type of tuberculosis in children is the acute miliary form, which may develop in well-nourished infants. Tuberculosis in children is most often confounded with chronic broncho-pneumonia or enterocolitis. The early manifestations of the disease are progressive emaciation, fever, and the presence of râles throughout the lungs, but these are insufficient for purposes of discrimination. The terminal lesions include: (*a*) Extension of the tuberculous process in the bronchial lymph-nodes and the lungs, resulting in the formation of abscesses, cavities, etc.; (*b*) diffusion of the tuberculous infection, constituting acute miliary tuberculosis, the principal viscera being affected in the following order: spleen, liver, brain, kidney, heart. The involvement of the brain is most important, the meningitis being regularly fatal. (*c*) When bone is involved and there is prolonged suppuration, waxy degeneration of the viscera may take place.

**Crossed Aphasia.**—Bramwell (*Lancet*, June 3, 1899) designates as crossed aphasia the condition in which an attack of right-sided hemiplegia in a left-handed person is attended with inability to express thought in language; and he reports an illustrative case. In this connection he points out (1) that the vast majority of mankind use one hand more than the other; (2) that the great majority are right-handed; (3) that the ancestors of the great majority of persons have for generations been right-handed; (4) that heredity, congenital organic aptitude, and actual acquirement, all tend to make the majority of persons right-handed; (5) that in right-handed persons the left hemisphere, and in left-handed persons the right hemisphere, is the real, or driving, side of the brain; (6) that with rare exceptions the leading or driving speech-centres are situated in the hemisphere of the brain, that is, so far as the movements of the hands are concerned, the leading or driving side; (7) that acute and complete destruction of Broca's convolution, when it occurs in a right-handed person, will, and does in a vast number of persons, produce motor vocal aphasia, while the same lesion, when it occurs in the left-handed person, will not, and does not in most cases, produce motor vocal aphasia. Conversely, acute and complete destruction of the motor vocal speech-centre in the right hemisphere of the brain, when it occurs in a left-handed person, will, and does in most cases, produce motor vocal aphasia, while the same lesion, when it occurs in a right-handed person, will not, and does not in the vast majority of cases, produce motor vocal aphasia. The exceptions to these statements constitute crossed aphasia. In the vast majority of cases of this kind the speech-defect is merely temporary and evanescent. Occasionally, though rarely, the aphasic symptoms are of long duration, *i.e.*, are persistent or permanent. Cases of the latter kind almost always occur in left-handed persons.

In the restoration of speech in the cases under consideration a distinction must be drawn between those in which Broca's centre is suddenly destroyed, and those in which the destruction is accomplished slowly and gradually. In the latter cases it is suggested that the opposite motor vocal speech centre was from the first, *i.e.*, immediately after the occurrence of the lesion, and without any process of training or substitution, sufficiently educated and active to take up and independently carry on the speech function, when the normally leading or driving speech-centre of the other hemisphere was destroyed. In cases in which the destruction is produced slowly and gradually, *i.e.*, by neoplasm, the most reasonable explanation seems to be that, *pari passu* with the destruction of the leading or driving motor vocal speech-centre, the corresponding and hitherto non-leading motor vocal centre becomes educated and trained so that even if the destruction is complete this centre is able to carry on independently the function of the leading speech-centre when that is destroyed.

**A New Micrococcus in Endocarditis.**—MacCallum and Hastings (*Centralblatt fur Bakteriologie u. Parasitenkunde*, March 28, 1899) describe a new micrococcus, which they name micrococcus symogène, isolated from the blood during life and from septic infarctions of the aortic valves after death in a case of acute endocarditis in a man aged thirty-seven years. The morphology is that of a micrococcus, resembling when grown on nutrient gelatin the pneumococcus. It stains by Gram's method, liquefies gelatin, and pep-

tonizes milk, after having rendered it acid and coagulated it. The organism is pathogenic for rabbits, dogs, and white mice. The lesions in the dog, following experimental infection, were strikingly similar to those found in man. Venous injection of the coccus set up a septic endocarditis with aortic involvement from which the organism was recovered. In man, as in the dog, the organism was found throughout most of the organs of the body.

**Methylene Blue in Insanity.**—The action of methylene blue in various psychoses is reported upon by P. Bodoni, of Genoa, in the *Klinisch-therapeutische Wochenschrift*, 1899, No. 21, May. He has found that intramuscular injections of from 0.8 to 0.1 gm. (gr. i. to iss.) produced markedly quieting effects in many forms of psychical excitement. He gives the clinical histories of cases of mania of various types, melancholia, dementia, paranoia, and hystero-epilepsy. Most of the cases were influenced by it, and he claims that it should take an important place, ranging with the more usually employed hypnotics, chloral, amylene hydrate, sulphonal, bromoform, and others.

**Etiology of Leukæmia.**—M. Löwit, of Innspruck, presents a somewhat startling series of conclusions with reference to the causation of leukæmia (*Centralblatt fur Bakteriologie u. Parasitenkunde*, vol. 25, No. 819, 1899, p. 273). He concludes that: (1) In myelæmia, there is to be found in the peripheral circulation an animal, or sporozoon, which he designates "hæmamœba leukæmia." This can reproduce itself by sporulation. In the blood-forming organs these spores are to be found having the characters of permanent spores. (2) In lymphæmia, on the contrary, parasites are rare. There is to be found in the blood-forming organs, however, an "hæmamœba magna," which the author proposes to call "hæmamœba leukæmia vivax." It is intracellular and probably intranuclear. (3) In some cases of leukæmia both types of parasite are found. (4) In infantile pseudo-leukæmic anæmia and in the adult three parasites may be found in the blood. (5) In susceptible animals the artificial infection and transmission from one animal to another is possible. In such infected animals a process is set up similar in many respects to that seen in man. The animals gradually lose strength and usually die after a few months. The amœba may be found in their blood, and more readily in the organs, which may have become hypertrophied. (6) Leukæmia may be inoculated from one animal to another. (7) The culture of the amœba in artificial media has not yet resulted in success.

**The Toxicity of the Urine in Pregnancy.**—Drs. Labadie-Lagrave, E. Boix, and J. Noe (*Archives Générales de Médecine*, May, 1899) publish the results of a series of urotoxic experiments on the blood of pregnant women. The method of experimentation followed was that of Bouchard. Their general results are that about a month or six weeks after pregnancy the toxic coefficient of the urine is about normal (0.46), and from that time to the third month it steadily becomes less, when it reaches 0.20 and maintains that percentage until confinement, in from a month to six weeks after the confinement the toxicity again rises to the normal. If the toxicity during the later months of pregnancy should rise to the normal figures, eclamptic attacks ought to be expected.

**Elimination from the Skin.**—Wakelin Barratt (*Journal of Physiology*, vol. 24, 1899) presents the results of an extended research on the influence of varnishing the skin and determining the effect on the transmission of water and carbon dioxide. Flexible collodion was used as a varnishing medium. He shows that when the skin is varnished the elimination of water is diminished but not abolished, the diminution amounting to about seventy-eight per cent. of the normal amount. The behavior of the skin in dry inflammation was shown to be similar, the diminution in this condition in the experiments made amounting to fifty-six per cent. In both cases the diminution was due to mechanical blocking up of the sweat ducts.

**The Bacteriology of Gangrene.**—A number of organisms have been isolated from gangrene, and the present communication of D. Rath, of the Strasburg University (*Centralblatt fur Bakteriologie*, 25, 1899), is of interest in that it records, so the author states, for the first time, the finding of bacillus lactis aerogenes in the gangrenous tissues.

**Spinal Muscular Atrophy.**—Siemerling (*Archiv fur Psychiatrie*, vol. 30, 1898-99, No. 1) contributes a complete history with report of microscopical findings of a case of this interesting and rare form of muscular atrophy. The history is of a young man twenty years of age, with no special family hereditary influences. Up to the age of five years he developed normally. At this time there commenced an atrophy of the small muscles of the lower extremities, and two years later the hands commenced to be involved. The atrophy progressed until at the age of thirteen he was unable to walk. He later developed hypochondriasis. At the time of examination his intelligence was fair; there was some immobility of the pupils to light, no changes in the fundus, and extreme atrophy of the muscles of all four extremities. Knee jerks were absent. The right leg was in contracture at the knee joint. There was no club foot. He had complete paralysis in the lower extremities, less in the upper. There were fibrillary twitchings of the intercostal muscles, and loss of electrical contractility for both galvanic and faradic currents. Psychically there was marked hypochondriacal depression with delusions. The patient died in collapse. The microscopical analysis showed degeneration of the posterior and lateral columns, especially in the dorsal and lumbar regions. There was atrophy of the anterior horn cells, Clarke's columns, and the anterior roots. The posterior roots were intact in their extramedullary portion and in some parts of their intramedullary course. There was simple degeneration of the sensory and mixed nerves with atrophy of the musculature. The résumé of the microscopical findings was as follows: Disease of posterior columns, most marked in the lower dorsal regions. In the upper dorsal and cervical regions almost total degeneration of the central part of Goll's column. In the columns of Burdach the degeneration became markedly less as the upper cervical region was reached. There was degeneration of the lateral columns posteriorly and partly of the antero-lateral columns, the lesions being most marked in the lower dorsal and lumbar regions and decreasing upward. The cerebral ganglion cells showed no alterations. The muscles of the lower extremities were in a condition of extreme degeneration, the gastrocnemius showing advanced fatty changes. All of the peripheral nerves examined, namely the brachial, radial, median, ulnar, sciatic, crural, peroneal, and saphenous nerves were markedly degenerated. The author further gives a critical digest of the various theories accounting for the disease, and basing his opinion on this one case believes that the disease is one of intramedullary origin, the posterior roots being affected after their entrance into the spinal cord. He does not exclude, however, a peripheral origin for the disease.

## MALARIA AND THE POSSIBILITY OF ITS EXTIRPATION.

MALARIA is admitted on all hands to be the most widespread disease that attacks mankind; it is also probably the most fatal to life. In tropical and subtropical countries there is certainly no malady that claims so large a number of victims. For example, in Italy the statement was recently made upon unimpeachable authority, that "malaria" keeps nearly five million acres of ground from cultivation; it affects sixty-three provinces, and every year poisons about two million inhabitants, causing the death of fifteen thousand human beings. In Africa, in Asia, in South America—indeed in every part of the globe situated in the tropics, the effect of its ravages is almost beyond computation. However, these facts are too well known to need further discussion, and the thought that naturally arises in the mind of every intelligent person is, How is it then that science has not succeeded in devising means to check or stamp out a disease so inimical to the human race? The answer, which covers nearly the whole ground, is the simple one that until recently the cause of malaria has been obscure. Many theories have been set forth in explanation, the majority of which were more or less visionary and rested on no firm foundation, while the one that appears now to be most worthy of belief required further proof before being generally accepted.

Of course it has long been a matter of common knowledge—at least in the greater number of cases—that in those swampy districts in which malaria had formerly prevailed, and where an efficient system of drainage had been undertaken, malaria was quickly and effectually banished; but why this should be was only surmised. The fact, too, that malaria is produced by certain minute parasites in the blood has been for some considerable time well known to scientific men; whence they came, however, and their mode of entrance remained a mystery. To the Frenchman, Laveran, the credit is usually given of first publishing the theory that the mosquito is responsible for the introduction of this parasite into the human system. Dr. Patrick Manson followed this line of research and made public his opinions on the subject, which Major Ronald Ross has so far confirmed by experiments in India extending over a lengthy period. Such eminent authorities as Bignami, Grassi, and Bastianelli have declared themselves convinced that these views are in the main correct, and that in the bite of some species of the mosquito the solution of the malaria problem must be looked for. So much has already been written in regard to Manson's theory, and concerning the painstaking and acute investigations of Ross tending to prove the same, that it would be superfluous to touch further on that part of the question. Suffice it, then, to say that most distinguished scientific men are of one mind as to the mosquito being at any rate an important if not the chief factor in the dissemination of malaria. Major Ross, regarding this point as practically proven, suggests, in a lecture delivered by him to the students of the Liverpool School of Tropical Medicine, a method of extirpating malaria. He is of the opinion that this object will be attained if the mosquitoes which produce the disease can be exterminated. The fact must ever be borne in mind that no claim is made that every mosquito is capable of conveying the malarial infection. This would preclude all possibility of extirpating them. According to Grassi there are three species, all belonging to the genus Anopheles, which are in this way a menace to the health of man, while in India Ross demonstrated that one species of the same genus was able to convey the malarial germs. This species makes its home in and around isolated natural pools and puddles, which are used by them as breeding-places. Again, it is not proposed to attempt to obliterate the adult parasite-bearing mosquito, another impossible task. The end in view would probably be gained by finding out where they breed and by destroying the larvæ. The larvæ of the dangerous mosquito can be distinguished by the fact that they float flat on the surface of the water, and the adults themselves are remarkable in that, unlike the members of the commoner species, their wings are spotted. An infallible sign in the detection of their breeding-place is, says Ross, their invariable habit of congregating in large numbers in its near locality. When the breeding-place is discovered, the plan of campaign suggested by Ross is a wholesale "slaughter of the innocents" before they have reached the winged stage in their development, and the method proposed is to empty or drain the pieces of water which serve as their nurseries. Provided that the breeding pool is located correctly, this proceeding, although at first sight appearing to present almost insurmountable difficulties, will when regarded more closely be seen to be eminently feasible. The pieces of water selected by the dangerous mosquito as a breeding-place are always so circumscribed in area that they can be emptied or drained easily. Small collections of water are chosen for the reason that they contain no minnows (which look upon the embryo mosquito as a dainty tid-bit and devour it with gusto).

With the view of substantiating the efficacy of this mode of checking malaria, arrangements have been made for an expedition to start from Liverpool to Sierra Leone in August. The expedition will consist of Major Ross, Dr. Annett, and an experienced dipterologist, and will spend five weeks in Africa, and

will return next year and on future occasions. The extermination of malaria is a matter of almost as great import to Americans as to the British, for the fact should not be forgotten that not only is it prevalent in various sections of this country, but that both Cuba and the Philippine Islands are hotbeds of the disease. Therefore, there can be no doubt that the experiments of Ross and his *confrères* will be followed with intense interest here, and the United States will join with the European nations in wishing them every success in their efforts for the common good.

## INCISION INTO THE KIDNEY FOR ALBUMINURIA.

THERE are some forms of albuminuria in which the presence of the albumin depends entirely upon the congestion of the kidney, without at first any irreparable structural alteration in the gland substance of the organ. We see such forms sometimes in scarlet fever and in some other conditions, and an analogous form after severe contusions of the lumbar regions, with or without intracapsular rupture of the kidney. This albuminuria after injury does not depend entirely upon the blood which is present in the urine, but to a great extent upon an actual transfer of blood constituents such as occurs in cases in which the renal congestion is due to some systemic cause, as scarlet fever.

There are records of many cases of lumbar injury followed by hæmaturia and albuminuria in which a lumbar incision has been made and the capsule of the kidney opened with a view to relieve evident tension, the cause of which was either pus or the extravasated blood following the injury, and there are recorded some cases of albuminuria following infectious diseases in which lumbar incision has been made in order to reach pus which was supposed to be in or around the kidney. In some of these cases no pus has been found, but the kidney has felt tense and enlarged, and incision through its capsule and into its substance has been followed by free discharge of blood and urine, with relief of all symptoms and disappearance of the albumin. Mr. Reginald Harrison, in a paper published in the Transactions of the Medical Society of London, in 1897, and more recently (1899) printed in a collection of essays upon cognate subjects, has given us an interesting discussion of some instructive cases bearing upon this question. He describes three cases upon which he has operated, the first scarlatinal nephritis, the second nephritis due to continued exposure to cold and damp, and the third nephritis due apparently to influenza. In all these cases the lumbar incision was made under the impression that pus would be found, and not specifically to relieve tension by incising the kidney. In none of the cases was pus found, and in each case the albuminuria promptly ceased, and the urine became normal. Mr. Harrison was much impressed by this latter circumstance, and in his paper speaks encouragingly of the possibility of applying this method to the relief of appropriate cases of albuminuria, and he emphasizes the harmful effects of circulatory tension in the kidney as well as in other organs. We know that the kidney is a complex and very vascular organ which is quickly influenced by circulatory conditions—the quantity, quality, and tension of the blood stream—and we also know that acute congestion, if at all intense, is a common cause of albuminuria, whether the kidney is healthy or already the seat of inflammatory disease. Our means of relieving this congestion by drugs and external modes of treatment, such as cupping, are at best uncertain, and are slow when we consider that a patient may die in a few hours with suppression of urine from congestion which we are trying to relieve, and if we can have a safe and certain method so simple in the hands of the surgeon as lumbar incision, there can be no valid objection to its employment. What we have to do in this connection is to establish general rules for the selection of cases, and we will find that there are not many cases of albuminuria in which we could unhesitatingly recommend lumbar incision. Of course in the large class of patients with nephritis associated with cardiac, pulmonary, or hepatic disease, there is no prospect of benefit from such a procedure as this operation. The cases in which we should like to see this method attempted are such as are seen in scarlet fever when there is a distinct tendency toward suppression, or even when the case is one simply with slowly increasing signs of nephritis, cases in which there is a sudden complete or almost complete suppression from exposure in individuals who have not previously shown evidences of nephritis, and in some of the subacute forms of Bright's disease when the exacerbations to which these are subject occur.

The technique of the operation is simple, and involves a short incision through the capsule and into the substance of the kidney, then treatment by packing so as to allow free discharge of blood and urine. It is probably not necessary to make the incision on both sides, since incision on one side soon relieves one kidney, and the other is then benefited by having its work done for it, and probably in part also by the intimate nervous connection which exists between the two organs.

## THE DISMANTLING OF BUILDINGS IN THE YELLOW-FEVER SEASON.

MANY instances have occurred in which yellow fever has appeared to have originated from or rather to have owed its recrudescence to the dismantling in summer of old buildings that have been infected with the disease. This has recently been the case at Vera Cruz, where the present severe epidemic of yellow fever has been concomitant with the demolition or repairing of ancient structures. According to *Public Health Reports* of June 30th the surgeon-general of the Marine-Hospital service is so much impressed with the danger of this procedure that he has addressed a letter to the president of the State board of health of Louisiana, calling attention to the outbreak of yellow fever in Franklin, La., last year, which probably originated in the dismantling of an old house that had been infected the year previous, and also to the case in Ha-

vana harbor, where the dismantling of an old barge was followed by yellow fever in the crew of a vessel near by.

These views receive further confirmation from the report of the United States consul at Vera Cruz with regard to the epidemic in that town referred to above. An extract from the report reads as follows: "Early in the spring of last year the city council passed a resolution to have owners of property comply with an ordinance then existing, to repair and fix up buildings in the city. Most of the owners preferred, previous to doing so, to make such general repairs and alterations as were needed; hence they commenced to take out partitions, break down entire walls, remove roofs, etc., and coral rock, brick, stone, plaster, roofings, and débris were everywhere piled up in the streets in front of the houses being repaired. Since then there has not been in this city a street where one or more buildings were not undergoing a general repairing. It was then that yellow fever made its appearance, and as the work progressed the fever increased until it is now an epidemic."

The evidence, therefore, favoring the belief that the custom of interfering with buildings in which yellow fever has formerly been present is dangerous to the health of the community at large would seem to be fairly conclusive, and should commend itself to the notice of health officers in this country.

## DYSENTERY IN JAPAN.

This malady is peculiarly prevalent and fatal in Japan. In fact, of all the infectious diseases dysentery claims the largest number of victims as well as providing the longest death roll. In the *Jimmin* are some impressive statistics bearing out this truth. During the five years ended in 1897 the total number of persons attacked by eight infectious diseases in Japan was 938,216, and out of that aggregate no less than 552,109, or fifty-eight per cent., were dysentery patients. Further, the deaths from these eight diseases numbered 269,086, and of these 137,880, or fifty-one per cent., resulted from dysentery, so that every year 110,420 are attacked by and 27,578 succumb to dysentery. Tokio is the most unfortunate city in Japan as regards this malady. In the five-year period referred to above, the total number of persons who suffered from the eight diseases are 17,107. Of these 6,921 were attacked by dysentery. The total number of deaths was 5,298, the deaths due to dysentery being 2,148. Thus dysentery was the cause of illness in forty-per cent. of the cases, as well as the cause of the deaths in the same percentage. Tokio is far and away the most backward city in the Japanese empire as regards hygienic arrangements. The *Jimmin* gives figures of the expenditure made by some of the principal centres of population in Japan for 1896, by which is shown that Tokio spends less for purposes of sanitation than many towns much inferior in wealth and population. Japan has showed herself so progressive and so ready to adopt the methods of western civilization that it may be predicted that she will not suffer herself to lag behind the cities of Europe and America in matters pertaining to sanitation.

## News of the Week.

**Report of the Marine-Hospital Service Commission on the Etiology of Yellow Fever.**—Under date of November 8, 1897, Passed Assistant Surgeon (now Surgeon) Eugene Wasdin and Passed Assistant Surgeon H. D. Geddings were detailed, by authority of the Secretary of the Treasury and the President, as a commission to investigate in Havana the nature of yellow fever. The report embodies the work of the commission in fairly testing the claim of Professor Sanarelli, of Bologna, Italy, that the bacillus icteroides is the cause of yellow fever, and the conclusion is drawn that this famous scientist has isolated the true cause of the terrible scourge. This conclusion is based upon a careful bacteriological study, in the well-equipped laboratory of the Marine-Hospital Service in Havana, of twenty-two cases of disease diagnosed as yellow fever by the native physicians in attendance. Of these cases all were seen during the progress of the disease, and in fourteen of them the commission concurred in the diagnosis. Each case was the subject of careful bacteriological study before and, if practicable, after death. Of the fourteen cases diagnosed as yellow fever, the commission isolated the bacillus icteroides from thirteen, and in the case in which this organism escaped the observation of the commission it was isolated by an independent observer for whom tube cultures had been taken at an autopsy conducted by the commission. The commission, having preserved a number of cultures made at the isolation hospital in the city of New Orleans from cases seen during the epidemic of 1897, also isolated therefrom the bacillus icteroides in the proportion of 83.33 per cent. of the cases examined, the cultures having been made at autopsy. Thus the identity of the bacillus icteroides of our Southern States with that found in Cuba, and that sent the commission by Professor Sanarelli which was obtained in South America, was established. As a control of these examinations the commission made use of a number of patients suffering from diseases other than yellow fever, from which the blood, extracted in the same manner and treated in the same way, failed to yield any organism at all comparable to Sanarelli's. These diseases were representative of those usual to the city of Havana, and were seen during the same period of time in which the cases of yellow fever were under observation. The following are the conclusions arrived at by the commissioners as a result of these investigations and of numerous experiments on animals: (1) That the microorganism discovered by Professor Giuseppe Sanarelli, of the University of Bologna, Italy, and by him named "bacillus icteroides," is the cause of yellow fever. (2) That yellow fever is naturally infectious to certain animals, the degree varying with the species; that in some rodents local infection is very quickly followed by blood infection; and that, while in dogs and

rabbits there is no evidence of this subsequent invasion of the blood, monkeys react to the infection the same as man. (3) That infection takes place by way of the respiratory tract, the primary colonization in this tract giving rise to the earlier manifestations of the disease. (4) That in many cases of the disease, probably a majority, the primary infection, or colonization in the lungs, is followed by a "secondary infection," or a secondary colonization of this organism in the blood of the patient; this secondary infection may be complicated by the co-instantaneous passage of other organisms into the blood, or this complication may arise during the last hours of life. (5) That there is no evidence to support the theory advanced by Professor Sanarelli that this disease is primarily a septicæmia, inasmuch as cases do occur in which the bacillus icteroides cannot be found in the blood or organs in which it might be deposited therefrom. (6) That there exists no causal relationship between the bacillus "X" of Sternberg and this highly infectious disease; and that the bacillus "X" is frequently found in the intestinal contents of normal animals and of man, as well as in the urine and the bronchial secretion. (7) That, so far as the commission is aware, the bacillus icteroides has never been found in any body other than one infected with yellow fever; and that whatever may be the cultural similarities between this and other micro-organisms, it is characterized by a specificity which is distinctive. (8) That the bacillus icteroides is very susceptible to the influences injurious to bacterial life; and that its ready control by the processes of disinfection, chemical and mechanical, is assured. (9) That the bacillus icteroides produces *in vitro*, as well as *in vita*, a toxin of the most marked potency; and that, from our present knowledge, there exists a reasonable possibility of the ultimate production of an anti-serum more potent than that of Professor Sanarelli.

**The Plague in Portugal.**—The bubonic plague has appeared at Oporto, capital of the province of Douro, on the River Douro, one hundred and seventy-five miles northeast of Lisbon. Up to August 15th, there had been twenty-six cases and eleven deaths from the disease. The *Medical Press and Circular* of August 2d said that the disease had probably broken out in Oporto. For several weeks there had been a number of suspicious deaths in that city, a prominent symptom of the illness being swellings in the groins and axillæ. The outlook is not encouraging, for the wretched sanitary state of Oporto is notorious. Preventive medicine in Portugal is in a most elementary condition, and the ignorance and superstition of the population render special precautionary measures wellnigh hopeless. A despatch, dated August 14th, from Lisbon to *The Sun*, says that it has been officially declared that the bubonic plague exists there as well, but "the announcement is received with some scepticism."

**Compulsory Vaccination in Massachusetts.**—A case of smallpox was discovered last week at Everett, Mass., and because of the danger the board of health ordered that every one of the twenty-three thousand inhabitants be vaccinated. Printed notices were sent to every householder in the city to that effect, and stating that free vaccination would be performed at the city hall. The infected district was quarantined. There seems to have been no effective opposition by the antis to the order, if there are any such in the town.

**The Plague in the East.**—The epidemic at Poona in the Bombay Presidency, India, is daily becoming more virulent. Even the natives have become panic stricken and are fleeing to the country in all directions, and the streets are deserted. The number of deaths from plague in the Bombay Presidency during the second week in August was 3,450. In China the plague has appeared at Niu-Chwang, in the province of Leao-Tong, near the Gulf of Pe-Chi-Li, far to the north of where it has previously raged, and much nearer Peking. In Hong Kong there were twenty-three deaths from the plague during the week ending August 13th, and twenty-five new cases were reported.

**Health Conditions in Chicago.**—According to the health department, a very satisfactory feature of the public-health situation is the low relative rate of infant mortality. At this season of the year the deaths of children under one year of age usually average more than one-third the total deaths. During the week ending July 15th, the total deaths were five hundred and fifty-nine, of which number two hundred and sixteen, or thirty-eight per cent., were of children under one year of age. In the week ending July 22d, the proportion was thirty-six per cent.; July 29th, thirty-one per cent.; August 5th, twenty-nine per cent.; August 12th, twenty-three per cent.

**Reorganization of the Red Cross.**—A new constitution of the American Red Cross Society, recently drafted, provides for a division of the United States into districts, each of which will come under the jurisdiction of the officers of the district branch, which will in turn be governed by the national body, the headquarters of which will be in Washington. As soon as the organization is perfected work will at once be undertaken to establish local societies in all parts of the country. The work of the society in Cuba, that of establishing homes for the orphans of those killed in the revolution, is practically completed, and the orphans are now, for the most part, maintained by the municipalities in which they are situated. There will be but few other changes, and those of minor importance, in the new constitution.

**An International Tuberculosis Congress.**—The National (British) Association for the Prevention of Consumption suggests that another international congress for the study of tuberculosis be held in London in May, 1901.

**Drs. Senn and Brower,** of Chicago, have recently been in Hawaii. On July 22d, a luau in Hawaiian style was given in their honor by Drs. Day and Wood. In addition to the local medical men several of the surgeons of the hospital ship *Relief*, then in the harbor, were present.

**The Medical Association of Hawaii.**—The annual meeting of this association was held in Honolulu on the evenings of May 30 and 31 and June 1, 1899. At the first session the president's address was delivered by Dr. Wood, after which the election of officers was held with the following result: *President*, Dr. C. B. Cooper; *Vice-President*, Dr. F. R. Day, *Secretary*, Dr. C. L. Garvin; Drs. R. P. Myers and C. B. Wood, members of the executive committee to serve with the above-named officers. Dr. Marshall Wood, surgeon U. S. A., was elected an honorary member of the association. Reports of committees were read, and the session was then adjourned. On May 31st Drs. Posey, Hoffman, and Yuel were elected to membership. Dr. Humphris read a paper on tuberculosis, which was discussed generally. On motion of Dr. Meyers, a committee of three was appointed to take Dr. Humphris' paper and formulate a report, using the same as a basis, to be published in pamphlet form in English, Hawaiian, Chinese, and Portuguese. This report will dwell on the treatment and prevention of the disease. Dr. Marshall Wood then presented some pathological specimens of typhoid fever, and discussed the treatment and prophylaxis of the disease. At the final session Dr. Hoffman reported some surgical cases, and Dr. W. E. Taylor related a case of gastrotomy performed for the removal of a number of pieces of broken glass and crockery which had been swallowed by a woman. In a discussion on the fevers of Hawaii it was stated that typhoid fever had appeared there only within the past two or three years. The annual banquet took place after adjournment, at the Pacific Club. It was decided to hold a meeting of the association on the first Saturday of each month, beginning in July.

**The Yellow-Fever Epidemic in Mexico.**—A report from the Texas State board of health on August 14th states that the yellow fever in Cordoba and Orizaba, Mexico, is increasing in intensity and virulence. The inspector of the Marine Hospital reports that the disease has appeared at Tuxpan, and that there were twenty deaths there up to the end of July. In Vera Cruz the disease is reported to be declining, and at Tampico, it is declared, no cases of the disease exist.

**A Study of Prostitution.**—The following are the names of those who have been delegated to investigate the conditions of prostitution in their respective countries, and to report at the International Congress on Syphilis, to be held at Brussels, September 4th and following days: Argentine Republic, Dr. Baldomero-Sommer, of Buenos Ayres; Austria, Dr. Finger, Vienna, Belgium, Drs. Bayet and J. Verhoogen, Brussels; Bosnia, Dr. Gluck, Savajovo; Chili, Dr. Valdes-Morel, Santiago; Denmark, Dr. Ehlers, Copenhagen; England, Drs. George Ogilvie and Drysdale, London; France, Drs. Ozenne and Julien, Paris; Germany, Drs. Blaschko, Berlin, and Neisser, Breslau; Hungary, Dr. Rona, Budapest; Holland, Dr. Selhorst, The Hague; Italy, Drs. Tommasoli, Palermo, and Bertavelli, Milan; Norway, Dr. Axel-Holst, Christiania; Roumania, Dr. Petrini de Garatz, Bucharest; Russia, Dr. Petersen, St. Petersburg; Sweden, Dr. Welander, Stockholm; Switzerland, Drs. Jadassohn and Schmid, of Berne; Turkey, Drs. Von During and Zotos, Constantinople; United States, Dr. Isadore Dyer, New Orleans.

**The "Occidental Medical Times"** and *The Pacific Record of Medicine and Surgery* have been consolidated under the title of the first-named journal. The editors of the combined journal will be Dr. Louis A. Kengla, of the *Times*, and Dr. James H. Parkinson, of the *Record*. The publication office will be removed from Sacramento to San Francisco.

**The Mercedes Hospital in Havana.**—An innovation in the management of hospitals in Havana was inaugurated on July 7th. On that day a children's ward was opened in the Mercedes Hospital. This was the first time that children in the hospitals of that city were placed in a ward by themselves. Formerly male children were placed in the male ward, and thus brought into contact with some of the worst classes of the human race. It was the same with girls in hospitals where women patients were received. But now, thanks to the energy and skill of Dr. Furbush, chief of the department of hospitals and charities, the sick children have their own ward, their own nurses, and their own doctors. The ward has beds for thirty children. Another new feature of the hospital is the woman's ward. Formerly Mercedes Hospital treated men only. But with the starting of the children's ward one for females was also added.

**The Juggernaut of New York.**—During the first six months of the present year fifty persons were killed in this city by the street cars, twenty-eight during the first quarter and twenty-two during the second. During the same period twenty-eight deaths resulted from railroad accidents in the city. The two hundred and fiftieth victim of the trolley cars in Brooklyn borough, since the lines were built, died last week.

**The Quarantine Against Hampton,** where there was recently an outbreak of yellow fever among the inmates of the Soldiers' Home, has now been raised, all fears of the spread of the disease having been removed.

**A New Naval Hospital at Mare Island.**—The old hospital at the Mare Island, Cal., navy yard, which was almost destroyed by earthquake several years ago, is now being replaced by a large modern structure. The new building will be of two stories and basement, the central portion being of three stories, with two hundred and sixty feet front. The central building will be for the administration, the wards being in the two wings. There will be dressing-rooms for minor cases at the extremities of each of the main wings, attached to the wards, and in the upper part of the central structure there are private rooms for invalid officers. In the rear will be a separate building connected by a covered way on each story with the main building. It will contain the kitchen and lavatories below, the dispensary and operating-rooms on the first floor, and the chapel in the upper story.

**Baltimore Sweat Shops.**—The Health Commissioner of Baltimore, Md., will shortly begin an investigation of the sweat shops with the view of preventing the spread of contagious diseases.

**Deaths in the Army.**—The following table, recently made public by the adjutant-general of the United States army, shows the number of deaths of soldiers from May 1, 1898, to June 30, 1899:

| | Killed. | | Died of Wounds. | | Died of Disease, Etc. | | Totals. |
|---|---|---|---|---|---|---|---|
| | Officers | Men. | Officers. | Men. | Officers. | Men. | |
| Cuba | 21 | 223 | 10 | 64 | 34 | 889 | 1,240 |
| Porto Rico | .. | 4 | .. | 8 | 4 | 251 | 267 |
| Philippines | 20 | 253 | 10 | 82 | 11 | 369 | 725 |
| Hawaii | .. | .. | .. | .. | .. | 46 | 46 |
| At sea | .. | .. | .. | 7 | 9 | 204 | 220 |
| United States. | 1 | 5 | 2 | 6 | 106 | 3,985 | 4,105 |
| Totals | 42 | 485 | 22 | 167 | 164 | 5,743 | 6,603 |

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending August 12, 1899. August 5th.—Medical Inspector J. R. Waggener promoted to medical inspector from April 9, 1899; Medical Inspector T. H. Streets promoted to medical inspector from April 16, 1899; Surgeon T. A. Berryhill promoted to surgeon from April 9, 1899; Surgeon E. P. Stone promoted to surgeon from April 16, 1899. August 8th.—Passed Assistant Surgeon J. M. Moore ordered to the *Vermont*, August 10th; Assistant Surgeon B. L. Wright detached from the *Vermont* and ordered to duty with the Second Marine battalion for Manila, P. I., and on arrival at Manila to report to the commander-in-chief of the Asiatic station for duty. August 9th.—Passed Assistant Surgeon W. F. Arnold granted extension of sick leave for one month; Passed Assistant Surgeon G. Pickrell authorized to drop middle initial of name. August 10th.—Passed Assistant Surgeon G. Pickrell detached from the *Baltimore* and ordered to the *Monterey* and to the Cavite naval station; Assistant Surgeon H. H. Haas detached from the *Oregon* and ordered to the naval hospital, Yokohama, Japan, for treatment.

**Disposal of the Dead by Liquid Air.**—It is said that a company has been formed in this city which will erect a crematory near Nyack, where the rapid consumption of dead bodies will be effected by means of liquid air.

**Death Rather than a Bath.**—A prisoner in a Jersey City jail persistently refused to take a bath, but was finally told that he would be forced to wash himself. He still refused, and the next morning was found dead in his cell, having killed himself.

**Death by Electricity.** Four firemen, while at work at a fire in Omaha recently, were killed by an electric shock. When the fire had been brought under control the firemen set to work to lower the extension ladder upon which they had been working. Suddenly there was a flash, and the four men who were working at the crank lowering the ladder fell to the pavement apparently lifeless. The ladder had come in contact with a live electric-light wire carrying a current of two thousand volts. The men were carried into an adjoining building and every effort was made to resuscitate them. One seemingly revived, but fell dead in a few minutes, but the others did not regain consciousness.

**Obituary Notes.**—Dr. Nathaniel Wilson Leighton died on August 12th, at his home in Brooklyn, after a brief illness. He was sixty-six years old and was born in Falmouth, Me. He was graduated from the Medical School of Maine, at Bowdoin College, in 1857, and from the now defunct New York Medical College in 1858. He was house physician and surgeon at the Kings County Hospital in 1859, and later at the Eastern District Hospital. He served during the Civil War on the army medical staff and received the brevet commission of lieutenant-colonel in 1864. He then resumed practice in Brooklyn and was for twenty years a pension examining surgeon. He is survived by two daughters and three sons.—Dr. F. H. Fincke, of Baltimore, a member of Commissioner-General Peck's staff, died at Chicago on August 13th, of heart disease. He had been assigned to duty as expert in medicine, dentistry, and chemistry in the Department of Liberal Arts and Chemical Industries at the Paris Exposition.—Dr. James L. Kortright died on August 14th, at Middletown, N. Y. He was born in Brooklyn in 1859, and was a graduate of the College of Physicians and Surgeons in this city in 1881. He practised in Brooklyn, where he was one of the visiting staff of St. Catherine's Hospital, until about a year ago, when he removed to Middletown in the hope of obtaining relief from pulmonary trouble. He leaves a widow and two children.—Dr. Joseph Coblentz, formerly of Reading, Pa., died on August 6th, at Vaughn, Wash., at the age of seventy-two years.—Dr. Andrew K. Smith, Surgeon U. S. A., retired, died of apoplexy on August 14th, at Highland Falls. He was born in Connecticut and was a graduate of Jefferson Medical College in 1849. He entered the army medical service in 1853. He was retired in 1890, and had since resided in this city. A widow and a daughter survive him.—Dr. George W. Ammon died suddenly at Reading, Pa., on August 13th, at the age of thirty-seven years. He was a graduate of Jefferson Medical College in the class of 1888.—Dr. Samuel B. Gilmore died at Philadelphia on August 13th, of typhoid fever, at the age of twenty-three years. He was graduated from the medical department of the University of Pennsylvania at its recent commencement.—Dr. Tunis L. Schenck, of Brooklyn, died suddenly on August 15th, of Bright's disease, at the age of fifty-eight years. He was born in Flatbush, and was graduated in medicine from the College of Physicians and Surgeons in this city in 1865.—Dr. Edward T. Shepard, of New Orleans died on August 15th, at the age of fifty-five years. He was born in Cincinnati, but went to New Orleans, in early life, and was a graduate of the medical department of the University of Louisiana in 1867. He was one of the physicians to the Louisiana Retreat for the Insane, and was at one time a member of the board of administration of Charity Hospital.

## Society Reports.

### THE BRITISH MEDICAL ASSOCIATION.

*Sixty-Seventh Annual Meeting, Held at Portsmouth, August 1, 2, 3, and 4, 1899.*

(Special Report for the MEDICAL RECORD)

GENERAL SESSIONS.

*First Day—Tuesday, August 1st.*

THE proceedings began by a meeting of the council at 9:30 A.M. This, which was private, was followed at 11 A.M. by two religious services, one at the Church of St. Mary, Southsea, where a sermon was preached by the Right Reverend Bishop of Winchester, and the other at the Roman Catholic Cathedral, where there was high mass followed by a sermon by the Rt. Rev. Monsignor Cahill.

The first general meeting of the association commenced at two o'clock The president of the council announced the absence of the president, Sir Thomas Grainger Stewart, through ill-health, upon which a vote of condolence was passed.

DR. WARD COUSINS, on taking the chair as president-elect, alluded in feeling terms to the regretted absence of his predecessor and proposed that a telegram should be sent to him expressing the hope that he would be speedily restored and regretting his enforced absence. This was carried with acclamation. Dr. Ward Cousins expressed his high appreciation of the honor the association had conferred upon him, and said that the town of Portsmouth would do what it could to entertain them in a suitable manner, and he (the president) hoped they would combine scientific discussion with amusement.

**Address of Welcome.**—The mayor, aldermen, and council of Portsmouth then entered, and the mayor, addressing the meeting, said that in the name of the corporation of Portsmouth he extended a hearty welcome to the British Medical Association. Portsmouth was not a great educational centre, but it nevertheless possessed not a few advantages, and would in no sense be described as a mean town, for it was the headquarters of the British navy, had unrivalled dockyards, and stores sufficient to equip the largest fleet that could be assembled. Some of the famous old "wooden walls" of England were in their possession, and some of the newest pattern; they had armed forts of a unique character in the bay, and they could boast of Haslar Hospital and Training College for the navy, and Netley for the army. He trusted that their deliberations would result alike to the advantage of the medical profession and the general welfare of mankind. In addition, Portsmouth was a busy town and a favorite watering-place and seaside resort. He, the mayor, in common with all his fellow-townsmen, were proud of the honor conferred on Dr. Ward Cousins, whom he heartily congratulated upon attaining the highest position it was in the power of the profession to bestow, and Portsmouth joined him in wishing the association a very successful conference under the presidency of their distinguished fellow-citizen.

**Report of the Council.**—DR. SAUNDBY, when the mayor and corporation had retired, moved the adoption of the annual report. They had just had, he said, a most prosperous year, financially, and their revenue might fairly be described as enormous, £42,924, against liabilities £38,188, leaving a surplus of £4,736. The council of the association had not been idle in other respects, for when the London Chamber of Commerce levelled at the medical profession the accusation of taking secret commissions, not only from druggists and chemists and other tradesmen, but from undertakers, the association after making strict inquiries could obtain no evidence that substantiated the accusation and called on the London Chamber of Commerce to prove their allegation; but that body merely replied by acknowledging the receipt of the communication, and the council repudiated with indignation the unfounded accusation that any number, if indeed any, of medical men were in the habit of going about with an undertaker's card in their pockets, debating which would be the more profitable course, to cure the patient or let him die and pocket the undertaker's commission. Monstrous!

The council had under consideration the mode of registration of medical men in the different parts of the empire, and application had been made to the India and colonial offices to inquire into the system of registration in the various dependencies of the empire. To which the former replied that there is no system in India; but the colonial office replied, offering, if the association would specify precisely the particular kind of information required, that the colonial secretary would address a circular despatch to the governors of all the colonies requesting them to supply it. This was done, and the matter was still under consideration.

The question of the inadequacy of the fees paid to medical witnesses was under the consideration of the parliamentary bills committee, and a memorial upon the subject had been drawn up and presented to the Home Secretary, to which that official replied by stating that he could not receive a deputation on the subject, nor did he think any useful purpose would be gained by so doing.

The Secretary for the Colonies had the fact brought before him that in Jamaica medical men were obliged, under a penalty of 40*s*., to notify infectious diseases, but were not awarded any remuneration for the duty thus imposed, and replied that he had instructed the governor of that colony to remedy the defect by introducing a law to provide for the payment of fees to medical men for notifying infectious diseases and to protect them from any legal consequences of such notification.

A new research scholarship had been founded in memory of the late editor, Mr. Ernest Hart, of the annual value of £200.

Venereal disease, said the chairman of the council, was a burning question that required to be carefully handled. A committee had been appointed to consider the subject, and a memorial sent to the government on behalf of the association, urging the appointment of a departmental committee to discover how great the evil was, and to express opinions as to any means that could be devised for preventing or limiting the spread of venereal disease among the civil population of the country; but no step in this direction had yet been taken by the government.

The members of the council of the association were not in a hurry as regards the midwives bill, but were watching carefully the proposed legislation on the subject. A resolution was drafted and sent to the General Medical Council, to each member of the House of Commons, and to the principal newspapers in London and the provinces. The council had since learned that the midwives bill had been abandoned for this session.

The president of the council then moved the adoption of the report. The treasurer of the association seconded, and stated that their assets were more valuable this year than last; the revenue for next year was promising, but there was, he regretted to say, a disposition on the part of some members of the association to shirk the payment of their subscriptions. It would be noted that the expenses connected with the printing and distribution of the journal amounted to £21,664.

and the amount received for subscriptions was only £19,598; but, on the other hand, advertisements brought in a further sum of £19,325, so that the journal paid for itself, a result due to the excellent business capacity of all concerned in its production.

Dr. Hartley proposed that the various items of the report should be taken in detail. His principal objection was that the cost of printing the advertisements was greater than the amount expended on the literary portion of the journal, and that the two accounts should be kept separately. The motion was seconded, and on being put to the meeting was rejected on a show of hands by a large majority.

Mr. George Brown objected to the statement that the midwives bill prepared by the association had been brought before the House of Commons, which was considering another bill the passing of which would be a disaster, not only for the medical profession, but for the public. It was promoted by the Midwives' Institution and a few gynecologists, and although it had been adopted by Mr. Balfour it did not represent the views of medical men. It was time that the British Medical Association took strong and concerted action in the matter. He moved a resolution to that effect.

Mr. Victor Horsley traversed Mr. Brown's statement and stated that the bill repudiated medical control over midwives, and that Mr. Johnson, M.P., who introduced a deputation to the lord president of the privy council, stated that medical men approved of it, but the general public had no idea of the aspirations of the Midwives' Association, and he had heard Mrs. Jacob Bright state that the midwives would not rest satisfied until they had a distinct and independent status.

Dr. Brierley thought the mischief was exaggerated, although the Duke of Devonshire had twice declined to hear the medical profession in opposition to the proposed midwives bill. No other profession or trade stand would such arrogant treatment at the hand of a cabinet minister.

It was then proposed that Mr. Brown's resolution be adopted with the rider added by Dr. Brierley, and this was carried.

Dr. Crocker proposed a vote of thanks to the retiring treasurer of the association, Dr. Charles Parsons, for his services during his term of office, and he was elected a vice-president of the association for life. He had been appointed in his absence three years ago when the meeting of the association was held at Carlisle, and in returning thanks he said that it was a matter of no small satisfaction to him that he left the association in a very flourishing condition and the owners of their own freehold premises in London, where they had forty men at work in the printing department, and a considerable number of clerks, two of whom were young women. Thanks to Mr. Fowkes, the general manager, everything worked smoothly, and when that gentleman came to retire, as in time he must, he (Dr. Parsons) hoped the association would let him do so on a handsome pension which he certainly deserved, for the association owed him more than the bulk of its members perhaps realized.

Mr. Butlin proposed Mr. Andrew Clark as treasurer, who, he said, was practically the minister of finance of the association. The nomination was duly seconded, and Mr. Clark was unanimously appointed treasurer of the British Medical Association, and duly returned thanks. He is not such a good speaker as Dr. Parsons, but no doubt will improve with practice.

Dr. Muir then complained that Scottish medical officers were completely at the mercy of the local district councils, from whose decision, no matter how contrary to right and justice, there was no appeal. He told of a recent glaring instance of oppression on the part of a district council in Scotland, and moved that the victim be assured of the sympathy of the association. As this was merely a "pious opinion," it was carried.

Mr. Victor Horsley then moved: That any draft bill for the amendment of the medical acts shall contain *inter alia* provision for further direct representation of the profession in the General Medical Council and for the establishment of a one-portal system of qualifying examination. There were, he said, two ways of getting what they wanted: first, to ask parliament to make the council an elective body, which, however, they were not likely to grant; and, secondly, to carry out the provisions of the medical acts of 1855–56. He thought the action of the British Medical Association in this matter had been discreditable, and on some protests being made he repeated the epithet, and said no other was applicable under the circumstances. This question had been considered at a special meeting of the council, when the following resolution was passed:

"*Resolved*, That the medical acts amendment bill as amended be referred back to the parliamentary bills committee with a request that they redraft the bill and submit it to a future meeting of the council."

The matter was reconsidered by the committee and the following resolution passed:

"That the sub-committee on the medical acts amendment bill be appointed to reconsider and amend, if necessary, the draft bill of the parliamentary bills committee."

This was done, and Mr. Horsley complained that the bill was emasculated and rendered worthless. Dr. Saundby suggested cut in two, but Mr. Horsley insisted on the word he had selected to signify the action of the committe toward the bill.

Dr. Brierley seconded the resolution, which was carried after it had received the support of Dr. Walker. This gentleman was also of opinion that the British Medical Association should have a representative in the House of Commons, and thought they might usefully employ part of their large surplus in sending Mr. Victor Horsley to Parliament to represent them.

The suggestion was not favorably received by the meeting.

Dr. Crocker gave his account of the action of the council: they did fight for the amendment bill, and Dr. Pope said that as regards the representation of the profession in the General Medical Council, if it had been insisted on, they would have lost the whole of their Irish members and many of those from London. This remark seemed to cause annoyance to a gentleman at the back of the hall, who shouted "Let 'em go, we don't want 'em!" which was received with laughter and tokens of dissent.

**The Indian Medical Service.**—Dr. T. M. Nair, of Madras, had given notice that he would move the following: That the present constitution of the civil medical service of India, whereby all important, educational, scientific, and sanitary appointments are exclusively reserved for members of a military medical service, namely, the Indian medical service, who are only lent for civil works till required for war purposes—is wrong in principle, prejudicial to the interests of medical education, science, and sanitation, and unsuited to existing conditions and requirements; and that in the interests of medical education and sanitation in India, and for the general advancement of medical science, the civil medical department should cease to be an appendage of, or a close reserve for, a military service, and all educational, scientific, and sanitary appointments in the department should be thrown open to the best talent available from the open profession of medicine.

As Dr. Nair was not present to move his resolution,

it was moved by Dr. Sarat K. Mullick who added some grateful appreciation of the work done by the military medical service of India, which, he said, had created the science of medicine in India.

The resolution was seconded by Dr. Potter, who had nothing good to say of his fellow-countrymen, but stated that the Indian government put incompetent men into posts simply because they were military men. He instanced the case of a professor of midwifery whom he had to call in consultation, and who admitted that he knew nothing whatever practically of the branch of the profession he was supposed to teach.

General Harvey, director of the military medical service in India, said he could not remain silent and hear that service maligned; the civil medical service of India was open to every one through the door of competition, and instanced several cases in which medical men holding high appointments were not military men, while one was not even a subject of her majesty. The reason so many civil posts were occupied by military surgeons was because the government could not find any one else competent to fill them. Let those gentlemen who objected compete for the posts themselves, and if they came out first from the competition they would get the appointment.

Colonel McLeod, examiner at Netley, said that from his own experience the men who were appointed were wholly competent to fill the posts and to maintain the reputation of their predecessors. Moreover, in the great cities the medical appointments were in the hands of the corporations of those cities, mostly natives, and, strange to say, they all appointed Europeans. It was the business of a government to get the best men it could, and he must say he doubted the accuracy of the statement that had been made to the contrary.

This led to some angry exclamations from Dr. Potter, but the chairman intervened at once and stopped what had threatened to be a scene, though the heat was all on one side, and that not the military one.

Dr. Mullick then, in replying, acknowledged in very handsome terms his own personal obligations to General Harvey, and to Colonel McLeod, and repeated what he had already said about how much India owed to the military medical service; but, he said in concluding his remarks, he thought the time had come when others should have a chance. As he did not refer to the remarks made by his seconder, it may be presumed that he did not agree with him.

The resolution was then put to the meeting and lost, no doubt chiefly on account of the judicious advocacy of Dr. Potter.

**The President's Address.**—Dr. J. Ward Cousins, M.D., F.R.C.S., began with a review of medical progress from the beginning of the century, noting the discovery of vaccination and its results, the lessons of the cholera epidemic of 1848 and those of the Crimean war. He spoke of the wonderful results of the labors of Florence Nightingale in the way of hospital and nursing reform, and paid a tribute to the late editor of the *British Medical Journal*, Mr. Ernest Hart, who was a pioneer in preventive medicine, had labored with enthusiasm in the great questions of epidemic cholera, water-borne disease, vaccination, and many others, and had raised the *British Medical Journal* to the position it now occupied.

**Pathology.**—The early part of the century was the period when the chasm between morbid anatomy and living pathology began to be bridged over. The old humoral theories of disease had been abandoned, and it was no longer believed that disease depended on an excess of bile, or blood, or phlegm, or other fluids of the body, and that it could be cured by getting rid of these elements. Hunter's pathology was a long way in advance of that of his predecessors, and he was the first to recognize that all the processes of the organism belonged to biological science. He saw that disease was only a deviation from health, and that both conditions were regulated by the same vital laws.

About 1830 great improvement took place in the manufacture of the microscope, and it was then that the value of microscopical examinations began to be generally appreciated.

Physiology then began to be everywhere recognized as the true basis of pathological study. In 1838 Schleiden made his brilliant discoveries in vegetable tissues, and soon after Schwann investigated the cellular structure of animal bodies. Although the progress of the century has been the outcome of the labors of many able workers, still, the speaker said, the first place should be given to Rudolph Virchow. We are indebted to him for exhibiting histology as the real instrument for unfolding the mysteries of disease. He practically gave to the world a new pathology founded on the results of observation and experiment. Every kind of organic structure and every new formation, he held, could be traced to a vital source, and he denied the possibility of spontaneous generation in either physiology or pathology. He recognized that every plastic exudation, which had been called amorphous material, contained living cells, and that these had come from living structures, and thus every new formation must be the offspring of some living tissue in which its living germs arose. The evolution of pathology has progressed side by side with that of biology, and we may say that, in its broadest sense, pathology is an outgrowth of biology. The work of the last fifty years has been a great unravelling of the relations between the healthy and the unhealthy phenomena of life. Through many years biology and pathology have been mutually helpful in their evolution, and we may rest assured that in the coming century their healthy reaction on each other will still go on. Pathology will advance, he said, and the new discoveries of biology will serve as starting-points of new pathological truths.

**Bacteriology.**—Recent investigations in bacteriology have been a great stimulus to the study of comparative pathology or the relations between the diseases of mankind and those of the lower animals. It was only a few years ago that the real nature of human tuberculosis was discovered, and its intimate association with a like disorder in domestic animals was demonstrated. Laennec was the first to describe tuberculous nodules, tracing their development from miliary tubercles. In 1865 the inoculation of animals with caseous material was found to produce in their bodies tubercles which were apparently similar to the disease in man. The probability of contagion was suggested, but that only excited ridicule at the time. Tuberculosis was generally regarded as an hereditary disease, but still external influences were looked on as powerful exciting causes. The microscope at that time failed to detect in the diseased parts any specific elements. Tubercle was examined by the keenest and best trained observers in the world, but it was pronounced to be so indefinite in structure that it could be recognized as much by negative as positive qualities.

In 1882 the whole pathology of the disease was revolutionized by the demonstration of the life history of the tubercle bacillus. The disease is now known to be a specific disorder, and the bacillus is the absolute proof of its invasion and the cause of the morbid changes. The inheritance of constitutional peculiarities, the liability to chronic inflammations, and the susceptibility to external influences are now regarded as simply conditions favoring the establishment of the microbe within the body, as auxiliary factors, which

are nevertheless no less potent because the specific characters of tuberculosis have been revealed.

Bacteriological investigation has already unfolded many of the problems connected with diphtheria. The researches began in Germany in 1882, the chief experiments being by Behring and Kitasato, who were soon followed by Roux, of the Pasteur Institute in Paris. We now know that many animals are liable to the attacks of this disease and that it is communicable to the horse, rabbit, guinea-pig, and fowls. Horses when attacked develop symptoms similar to those which follow inoculation of the diphtheritic toxin.

The bubonic plague which was epidemic throughout Europe during the Middle Ages has scourged India and the East during the last three years, and many workers have been led to make the disease the subject of special study. In 1894 a bacillus was discovered in the blood of a patient suffering from the plague. It is believed that rats are largely responsible for spreading the infection, squirrels and cats have been known to die of the disease, and it has recently been stated by a French observer that fleas are disseminators of the disease.

Ogsten in 1881 detected micro-organisms in acute abscesses, and this discovery has resulted in a demonstration of a direct connection between suppuration and pyogenic organisms. It is certain that the staphylococcus, the streptococcus, the bacillus coli communis, and others may be the exciting causes of septic conditions in man and the lower animals. Are the micro-organisms the direct cause of septicæmia or is it produced by the chemical substances which they elaborate? All animals appear to be liable to blood poisoning. Dr. Hewlett says that poultry, pigeons, pheasants, and sparrows are susceptible to a disease which Pasteur proved to be excited by a bacillus identical with the bacillus of rabbit septicæmia. Even the mouse has its specific septic disturbance, and the organisms which are present in its blood appear to be identical with those discovered in the septic disorders of swine.

**Malaria.**—This disease has been traced to a parasite which has the power of assuming a latent condition within the human body, living in the interior of the red blood corpuscles. Manson thinks that it is removed from the blood by some species of mosquito. The parasite is then propagated outside the human body. The insects infect their larvæ, and man is in turn, the speaker believed, infected by drinking the water contaminated by the mosquito, or by inhaling the dust of the dry mud of the pools in which mosquitoes have perished.

With all these advances, however, Dr. Cousins said, we were yet only touching the fringe of the possible revelations of bacteriology. Much that has been done will have to be done over again, and much that has been written will have to be rewritten. Many questions have yet to be solved. The striking differences in the susceptibility to disease of different individuals are still to be explained. Some seem to possess a natural insusceptibility to infectious disorders while others are susceptible on the smallest exposure. He did not believe that any individual can inherit or acquire an immunity from all forms of disease, although some races appear to acquire partial immunity from yellow fever and malaria. Race immunity is generally explained by natural selection and protection by inheritance. During the long periods susceptible persons were weeded out, and those that remained are capable of transmitting their insusceptibility. But we learn from experience the resisting-power to infectious diseases is very variable, and that there is no such thing as absolute immunity.

**Surgical Anæsthesia.**—"In the noontime of this Victorian era," Dr. Cousins said, "surgical anæsthesia was the brilliant gift to the civilized world by our brethren and kinsmen across the great Atlantic, and at the last annual meeting but one of this, the greatest of the centuries, we desire to record our admiration of the courage and genius of William Morton and the wisdom and surgical skill of Charles Collins Warren, and again to crown their memories with enduring fame as great benefactors of the human race."

The original anæsthetic agents still hold the confidence of the medical world, but there are many differences of opinion regarding them, and we may hope that soon safer remedies may be discovered. Sir James Simpson entertained this hope until the end of his career, and Dr. Snow, who did so much to perfect the administration of anæsthesia, believed that better agents could be found. Surgical anæsthesia, however, can never be wholly stripped of risk; but the risk is now greatly reduced by our modern safeguards and improved methods of administration. Before the introduction of anæsthetics operations were confined to cases in which they were absolutely necessary, and both patient and surgeon had to be brave and determined—one to suffer pain, and the other to perform delicate manipulations with rapidity and dexterity. The introduction of surgical anæsthesia exercised at once a great influence on the practice of surgery. Within six months the surgical work of the London hospitals was actually doubled, and in every department the domain of surgery rapidly extended. Unfortunately, the surgical world was quite unprepared for the sudden outburst which followed the great discovery. Surgical instruments were few in number, and very different from what they are to-day. Hospitals were for the most part constructed regardless of sanitary precautions, and without any means for securing adequate light and fresh air for the safe management of surgical cases and treatment of acute diseases. Nursing then meant nothing more than the attendance of a parcel of ignorant women who possessed no qualification for their duties, and who had never received a moment's training. It cannot be gainsaid that in those days thousands of lives were sacrificed to ignorance and superstition, and thousands more to inebriety and dirt. Under such conditions it is not surprising that suppuration occurred in almost every wound, and that septic processes were started by every operation.

The high mortality which occurred in the institutions both of Great Britain and on the Continent roused the profession to earnest investigation, and the unsanitary condition and many structural defects of the hospitals were soon revealed. Waves of gangrene, pyæmia, and erysipelas ran through the wards of these old buildings, and the medical officers saw clearly that these disorders were infectious and carried from one patient to another.

And now, Dr. Cousins said, his review had reached the dawn of another important epoch in the medical history of the century. The terrible ravages of sepsis helped to bring about better ward ventilation and improved sanitary arrangements in many of the old buildings. The evil of overcrowding was checked, and many reforms followed in the administrative and nursing departments. The technique of operative surgery was also improved. Water dressing or irrigation was used by some, others closed the wounds with friar's balsam; and others, after bringing together the cut integuments with plaster strips, used dry wool and pressure. There can be no doubt that greater cleanliness and new methods of treatment were introduced at this period with success, and these advances helped to prepare the surgical world for the time when the doctrines of Lister revolutionized the practice of surgery. Lord Lister demonstrated to the world the part that living organisms play in the production of septic

diseases, and disclosed the simple means by which their growth and development could be prevented. He proved that wounds could be made to heal by first intention, that the process of suppuration could be controlled, and that precautions easy of application would stop the development of septic disorders.

**Roentgen Rays.**—There is at this time no organ or region of the body which has not been investigated by the surgeon, and year by year his art has gained wider application, and reached a higher state of perfection by new methods of diagnosis and improvements in surgical technique. Only three and a half years ago the discovery of Professor Roentgen was communicated to the scientific world, and it has already revolutionized the old methods of military surgery, and rendered easy the location of metallic substances impacted in the body. It has given a fresh impulse to the study of diseases and deformities of the skeleton, and is an invaluable guide to the treatment of injuries and diseases of the epiphyses and joints.

**Hernia.**—The time is coming when there will be a considerable reduction in the number of adults suffering from hernial troubles, the speaker said, and this important result will be due to the improved technique of radical operations. There will also be a great reduction in the number of persons afflicted with loss of sight, the issue of the modern treatment of infantile ophthalmia and the corneal diseases of children, and also the early correction of errors of refraction.

**Adenoid Growths.**—During the last twenty-five years great advances have been made in aural surgery, and the number of deaf persons in the world has been greatly reduced. It took Dr. Hans Wilhelm Meyer some years to convince the profession that pharyngeal vegetations were a common cause not only of loss of hearing and obstructed nasal respiration, but also of defective articulation and impaired mental and bodily development. But he lived to see his discovery acknowledged, and it is no exaggeration to assert that the number of young persons who have been saved from life-long deafness by the removal of these obstructing glands amounts already to hundreds of thousands, and that hundreds of thousands more will be delivered from this terrible affliction in future times.

**Septicæmia.**—The true causation of human septic disease is still undetermined. Up to the present time the toxin of septicæmia has not been isolated, although the bodies of infected animals must contain a very powerful poison. The filtrates of streptococcus cultures have exhibited very little toxic action, and there is no very satisfactory evidence of their value in the treatment of septic diseases. The prevention of inoculation through a wounded surface is now possible, but when the disease is once fully established we are practically powerless to cure it. A remedy will doubtless in time be found, but at the present time we have no cure for sepsis when it has entered the body.

**Cancer.**—Dr. Cousins said that the treatment of cancer offers a great field for inquiry in coming years. Cancer is said to cause six or seven per cent. of the total deaths of both sexes over forty-five years, but these figures are probably rather under than over the real number. Recently some investigations have been published suggesting that the disease is due to a parasite, and Mr. Plummer states that he has discovered parasitic bodies in eleven hundred and thirty cases out of twelve hundred and seventy-eight. Local irritation is certainly a great factor in the development of cancer, and this may possibly favor the entrance and growth of the parasite. Other observers have suggested that the disorder is an infectious disease. A curative serum for carcinoma has not yet been discovered. Up to the present time surgical treatment yields the only good results, and the earlier it is adopted the better. Much good will doubtless come from improvement in our methods of diagnosis, so that the surgeon will be able to recognize the disease in its incipient stage. It is a satisfaction to know that many of the best pathologists and surgeons of the present day are diligently laboring in all parts of the world to unfold the mysteries which still surround this terrible disease.

The speaker then took up the question of preventive medicine, the battle for which is to be fought out chiefly in the dwellings of the working classes. Much, very much, must yet be done in the way of educating the public up to the recognition of the importance and absolute necessity of cleanliness and sanitary living.

Mr. Butlin, of St. Bartholomew's Hospital, moved a vote of thanks to the president, and said he came prepared to hear a good discourse, but he was not prepared for an ovation so full of facts and wise and able counsel as he had listened to.

Professor Ogston, of Aberdeen, seconded the vote of thanks, which was carried with acclamation.

---

## SECTION OF MEDICINE.

*First Day— Wednesday, August 2d.*

**The Treatment of Tuberculosis.**—Dr. T. Mitchell Bruce took this as the subject of his presidential address.

**The President's Address.**—Dr. T. Mitchell Bruce in opening the session outlined the work before the section. There were two subjects appointed for formal discussion, namely, (1) the medical tests required for admission to the public services, and (2) the prevention and treatment of tuberculosis. The first subject was one very naturally suggested by the place of meeting. Portsmouth, having long been one of the greatest military and naval centres in Great Britain, was associated in the minds of every one with the army and the fleet, and the choice of this subject would give an opportunity to the many members of the army and navy medical services to discuss something with which they were practically familiar, and on which therefore they could speak with the authority of experts. But the subject did not concern them alone, for all physicians, as loyal citizens, were deeply interested in the selection of the personnel to whom the interests and honor of the United Kingdom in its relation to other countries would be entrusted.

The question of the prophylaxis and treatment of tuberculosis was also not entirely foreign to Portsmouth, for on the other side of the Solent lay the Isle of Wight, and the places on this island and the coast region of the south of Hampshire and Dorset, with Netley, Southampton, the New Forest, Milford-on-Sea, Southbourne, Bournemouth, Swanage, and Weymouth, were the types of English winter quarters for the phthisical, rivalling in this respect the health resorts of Devon and Cornwall on the west, and of Sussex and Kent on the east. Here were to be found many members of the association whose time was devoted almost exclusively to the care of sufferers from consumption, many of the latter being entrusted to their guidance each winter by colleagues in the other parts of Great Britain. Naturally, he continued, this was the second direction in which the officers of this section turned for a subject of useful discussion; and, indeed, the extraordinary interest being manifested at present in the treatment of tuberculosis of itself justified the choice. And inasmuch as there now existed a firm basis of etiological and pathological facts on which to work, it was thought only proper not to confine the discussion to the bare question of treatment, but to study also the subject of prevention. Dr.

Bruce said that he expected great things from this discussion. It might be somewhat premature to inquire concerning the results of the open-air treatment of tuberculosis, at any rate in this country; but he was confident that the discussion would be entered upon with an enthusiasm begotten of the consciousness of rapidly increasing knowledge and of growing hope, and that in the hands of such masters as had promised to contribute to it, the discussion would be continued on a high level and prove a genuine practical success.

If the work about to be begun in the section should result on the one hand in an improvement in the quality and efficiency of the public services, and, on the other hand, in a reduction of the misery and waste wrought by tuberculosis, the speaker thought the members would be able to congratulate themselves on time profitably as well as pleasantly spent, and he looked forward with confidence to the outcome of the labors of the next three days.

**Medical Tests Required for Admission to the Public Services.**—Dr. T. D. Savill, in opening the set discussion on this subject, considered that the higher the type of the man the less chance he had of passing the tests and consequently of rejection from the army.

With regard to height, there was no doubt that five feet six inches (about the speaker's own height) was the best for all practical purposes: a shorter man could stand more fatigue and undergo more exertion than a taller man; the shorter man was capable of more endurance. A man might have every quality suitable for service in the army and yet be rejected on the one question of height. It would be a good thing if every young man was obliged to submit to military training for two years. See the Germans: what big, broad-shouldered athletic fellows they were, and how easy it was to tell a man who had been drilled from one who had not! There ought to be a general conscription enforced.

Dr. Sykes was of the opinion that the officers secured in the army were unsuitable; they were selected for their literary and scientific attainments and no account at all was taken of their physical capacity: the consequence was the wrong men were chosen. There was only one nation besides the British that chose its officers by literary tests, and that was the Chinese, and could anything be more inefficient than their army? There was no uniformity in the examinations. He (Dr. Sykes) knew of a young man who had a chronic abscess in his ear, had it well syringed, and passed the test examination; another, admirably fitted in every respect, had slight varicose veins and was rejected: had he gone to a civil hospital and been operated on, he would have been accepted. Chest measurement is a fallacious test. Say the minimum was thirty-five inches, and two men presented themselves for examination and passed, though one was six feet in height and the other five feet six inches; there was an immense difference in the physique of the two men, but because they had the requisite chest measurement they were passed. Why did the young officers die off in India? Because of their poor physique and consequent inability to sustain fatigue and resist the effects of the climate. "There is something rotten in the state of Denmark," said the speaker in conclusion, and the system urgently required revision.

Dr. Barr was of opinion that the best men were wanted, and thought it was a disastrous step to lower the standard of height and chest measurement in order to introduce into the service an inferior type of men. Brave men were wanted, not fellows with a pulse beating ninety strokes to the minute. So soon as he gets in a warm corner such a man is useless, mischievous even, for one coward with nerves will create a panic and destroy an army in action.

Surgeon-General Muir asked for information as to what points constitute a good standard. He thought that the amount of expansion of which a man's chest was capable would be a better test. Given two men of the same height, one with a chest expansion of two inches, and the other with a chest expansion of four inches, the latter would unquestionably be the better man. He thought that the physical examination should follow the literary, for the latter might break a man down and render him unfit for service. As regards height, what was the type of British manhood? It would be well to have that point established on a correct basis. What was wanted in soldiers and officers was endurance and not merely good shooting.

Surgeon-General Cuffe thought that the most suitable class of men came from the agricultural districts, but they were more difficult to get than was formerly the case. As a rule, very tall men have a poor chest measurement, but the ordinary run of agricultural recruits turned out well. The officers were deficient in physique very often, though eminently qualified from a literary point of view; but vacancies occurred, and it was necessary to fill them with the best men obtainable. With regard to "lame ducks," it was not the examiner's business, said the speaker, to accept them and by operating on them afterward make them efficient; but if they went to a civil hospital and got cured, then they might be accepted. The color test was a very important one, for a man would be of no use who could not distinguish signals; therefore, color-blindness quite unfitted a man for the service. Some candidates brought first-class certificates from men eminent in the profession, and had to be rejected by the examining surgeons because sufficient care had not been taken by the man who gave the certificate, or he had been imposed on. He instanced a case of a young man whose father was an influential member of parliament, who was certified as fit, and when examined he was found to have a lateral curvature of the spine. It was impossible for any one who was not acquainted with the routine of examining recruits to judge of a man's fitness for the service. A disease such as a minor amount of varicosity in the veins of the leg, for instance, would be taken advantage of by a lazy man as an excuse for shirking his duty; therefore it was essential not to accept any one suffering from such complaints as did not actually unfit him for the service, but nevertheless rendered him less capable of enduring an extra strain on the system.

Dr. Calwell thought it was a question of averages; but in examining for insurance, a person with "nerves" was not considered a first-class life. He had met with a man who might be described as a perfect specimen of humanity, but he was afflicted with nervousness and would not be accepted.

Colonel Welch, R.A.M.C., said personal appearance was an important consideration. What was wanted was the best that could be got—not perfection, which was unattainable; but it was seldom that even the most suitable was secured, often the reverse of that. The men who served the Queen were not the best specimens of their class and did not even represent the medium of the race to which they belong. A certain amount of literary acquirements was, of course, necessary, but physical qualifications were by no means undesirable, and should receive more consideration than they got. There was necessarily variation of results, for tests were elastic, and it was not fair to blame the examiners. If albuminuria (which had been mentioned as sufficient to insure the rejection of a candidate)—if albuminuria was associated with structural changes—well and good, it should be held sufficient to exclude a man from the army, but if it was merely functional, then it was not of so much consequence.

Chest measurement, as a rule, did not take the development of the muscular system into consideration; there should be a fixed standard of comparison in such cases, for there might be a great difference in the breathing capacity of two men that measured the same number of inches around the chest. A good test of fitness was the gradual elimination of the unfit: no lad under twenty should be accepted except as a probationer. The proportion of height to weight was very important, for increase of height unaccompanied by proportionate increase in weight and development was waste. He was of opinion that a couple of years' military training was of incalculable benefit to a man, especially as regards discipline.

Dr. Mitchell Bruce, in summing up the discussion, advised members to draw up some resolutions making a request of the war office in the name of the British Medical Association that the physical should precede the educational test; that soldiers should not be required to serve in the tropics under the age of twenty-two years; and that the physical standard for admission into the army should be reconsidered in the direction of raising and not of lowering.

**Hypertrophic Cirrhosis with Pigmentation.**—Dr. William Osler, of Baltimore, Md., read a paper with this title. The bronzing, he said, preceded the occurrence of diabetes, which was not an essential feature of the disease, but a late symptom that might be entirely absent. The pigmentation was not confined to the skin, but was distributed throughout the various organs of the body. He gave several cases: A patient complained of an enlargement of the liver and of a change of color: on examination the spleen was also found to be enlarged. He was in no pain, and was more concerned about his altered appearance than the increase in size of his liver, of which he was sensible. He was not an alcoholic subject, but had always been in good health. The first symptoms were noticed in 1895, and in 1896 when he again came under observation they had increased to a very marked degree, and there was considerable emaciation. Afterward erythema nodosum and purpura supervened, and the man died in 1897; he had ascites toward the close of his illness, but glycosuria never occurred. Professor Osler said it was this form of cirrhosis that was described in France as diabète bronzé, sans diabète.

The second case was that of a pilot, aged forty-eight years, who first applied for advice respecting the discoloration of his skin; he also had enlargement of the liver and spleen, but no glycosuria. He was not an abstainer, but had never been a heavy drinker, and had worked as a pilot for fourteen years, an occupation that requires a man to be careful and abstemious. He had never been exposed to malaria; at an early stage of his illness he had purpura and erythema, and in two years he had a recurrence of these complications more than one hundred times.

It was probable that this form of cirrhosis was a morbid entity associated with deterioration of the blood corpuscles, diabetes being quite a secondary complication. The essential difference between it and other forms of cirrhosis was the peculiar pigmentation by which it is characterized.

**Uric Acid and Its Effects.**—Dr. Alexander Haig then read a paper entitled "Uric Acid and the Circulation: Some New Methods of Estimating Its Effects." High blood pressure and defective capillary circulation, he said, were constant concomitant signs of the uric-acid headache. The headache was known to be due to uric acid, because all diet and drug treatment that relieved it diminished the amount of this substance in the blood and urine. The headache was due to the effects of high blood pressure on the cranial circulation. If Raynaud's disease was due to uric acid, it followed that similar but less marked alterations in the rate of the capillary reflux would be found corresponding with other and less marked alterations in the amount of uric acid in the blood. After a good deal of experimentation, he had adopted that test which gave a constant area of pressure, and he measured the duration of the pressure and the rate of the return of the color by means of a metronome beating half seconds. He further added to the test thus constituted an observation of the rate of disappearances of the after-image, or fatigue image of the retina, as a measure of the good or bad capillary circulation in the retina. He also observed and recorded in curves either the size of the radial artery by Oliver's arteriometer, or the blood pressure by the Still-Barnard sphygmometer, and the figures shown were thus obtained. A few months of daily observations proved that all of these things altered together; that slow capillary reflux went with high blood pressure, or dilated radial artery, and with slow disappearance of the after-image, or *vice versa*. Further, it showed that all these results followed exactly the well-known physiological fluctuations in the excretion of uric acid, the capillary reflux being slow in the morning and quick in the evening, and that these results corresponded with, and could be corroborated by, the examination of the urine, the examination of the granules in the blood, and the relation of surface to deep temperatures. In reference to drug action he soon found that, just as he had previously known that he could control the uric acid in the urine, the granules in the blood, and the relation of surface to deep temperature, so now he could control, also with absolute certainty, the capillary reflux, the retinal circulation, and the blood pressure, either from day to day or from hour to hour; that this could be done only by controlling the uric acid; but that if he failed to control the uric acid, he also failed to control the circulation and its results. Any one could duplicate the physiological results in his own person, as in every one living the ordinary life of this country the capillary reflux was at its slowest some time in the morning, and at its quickest some time in the evening; but if the normal uric-acid curves were altered, the capillary curves would follow. These tests were, singly or combined, indices of the amount of uric acid in the blood and urine, and this in the case of the capillary reflux could be estimated by any one without instruments and in ten seconds of time. Fever on the one hand, and Bright's disease on the other, are thus easily and quickly discriminated, and in the case of Bright's disease and diabetes attention was at once drawn to what he had long regarded as the central factor of these diseases, namely, defective capillary circulation and its consequence, defective combustion. These results showed that the observed relation between migraine with its slow pulse, high blood pressure, and defective capillary circulation, and an excess of uric acid in the blood and urine, was not an accidental coincidence, but a single instance of a general law. Uric acid controlled the capillary circulation of the body, and any accurate record of such capillary circulation was thus an index of the quantity of uric acid in the blood and urine.

No discussion followed the reading of this paper, which was illustrated by diagrams which were removed too quickly to admit of their being copied.

**The Gelatinous Form of Sodium Biurate and Its Bearing on the Pathology of Gout.**—Dr. Luff then read a paper with this title. He said that his experiments were conduced with artificial blood serum, which was easier to procure, and gave the same results as the genuine article. He found that sodium bicarbonate hastened the conversion of the gelatinous into the crystallized form of biurate, which explained why certain mineral waters actually bring on an attack

ot gout; but potassium bicarbonate produced an exactly opposite effect.

**The Nature and Treatment of Gout.**—Dr. Bain then read a paper entitled "An Experimental Contribution to the Study of Gout," and stated that extract of colchicum had no effect on the excretion of uric acid. He presented the following table embodying the results of some of his experiments, showing the excretion of uric acid under varying conditions.

| | Uric Acid | Bases |
|---|---|---|
| Fixed diet | .47 | .055 |
| Colchicum | .51 | .053 |
| Sod. salicyl | .62 | .037 |
| Spinach | .50 | .... |

When asked what constituted a "fixed diet," he replied: "Bread and butter, tea, beef-tea, meat, etc." He considered that sodium bicarbonate was a specific in the treatment of gout.

Dr. Sykes considered that lumbago was a form of gout, and always was relieved by a full dose of sodium bicarbonate.

Dr. Tyson, of Philadelphia, said that there was no subject more difficult to discuss than gout. In America it was not a very common disease, but in his hands sodium bicarbonate gave the best results, and he always gave it the first trial when called upon to prescribe for a patient suffering from an attack of gout; this was always relieved by a continuous use of soda drinks. Clinical experience, he thought, must determine the point.

Dr. Luff was of the opinion that the difference of the results in the experience of the gentleman who had spoken was due to the non-differentiation of gout and rheumatism. In arthritic cases he gave soda, and if it did no good the complaint was gout.

Dr. Bain thought that, in a disease supposed to be due to retention of uric acid in the system, it was a mistake to give a drug that increased the formation of that product. If he might venture to say so, he fancied Dr. Sykes' lumbago was of rheumatic origin—an insinuation which Dr. Sykes repelled with some warmth. It was gout, he said, and his father had had it before him.

The Chairman said that no doubt Dr. Sykes was the best judge of his own case.

---

## SECTION OF SURGERY.

*First Day—Wednesday, August 2d.*

**The President's Address.**—Mr. H. T. Butlin made a few introductory remarks, taking as his subject "The Work of the Section."

He said that the officers of the section had arranged for two subjects for formal discussion, the first being the diagnosis and treatment of gunshot wounds of the abdomen, and the second, the prevention and treatment of syphilis in the army and navy. The selection had been guided largely by the knowledge that there would be an unusual number of naval and military medical officers present at this meeting, and the speaker hoped that they would participate actively in the discussion. It had, indeed, been arranged that each of the subjects above mentioned should be introduced by a member of the medical corps of the army or navy. The discussions, however, should not be confined to the members of the medical service in either army or navy, for pains had been taken to select subjects of interest to civil as well as fighting medical men. Especially was this so in the case of the first of the set discussions. Many surgeons in civil life have abundant opportunity to study gunshot wounds of the abdomen, for of late years the use of firearms has increased alarmingly. If a man quarrels with a fellow-workman he gets a pistol and shoots him, or if a lad quarrels with his lass he shoots her, sometimes fatally; then turns the weapon against himself, but rarely with such success that he blows out the little brains he has. The statistics of St. Bartholomew's Hospital illustrated in a remarkable manner the increase in the number of wounds due to firearms. In the seventies and early eighties there was an average of about three cases in a year, but for some years past there have been eleven or twelve cases every year, and last year the speaker had under his own care four patients with bullet wounds of the chest. At this rate, he said, civil surgeons might hope soon to become as cunning in the diagnosis and treatment of gunshot wounds as their naval and military brethren. He did not know whether there was any essential difference in the character of gunshot wounds in civil and in military practice, but there was probably a great difference in the moral effect. The pistols used are very good, but some of them are little better than toys. A civilian shot point-blank and from a short distance was usually horribly frightened, fully expecting to die, so hospital surgeons had to deal with a mental distress much greater than that from which the soldier suffers from a wound which may or may not be dangerous in itself. The speaker was called one evening to see two young men who had been shot, each in the chest, and at very close quarters. One of them appeared seriously injured, and was very ill for several days. He breathed with difficulty, and made no outcry, but the other bewailed his fate in loud groans, and as the bullet had struck him full in the chest, and the assassin was only about four feet distant from him, he fully believed his time was come. When Mr. Butlin came to examine the man, however, he discovered that he presented no sign of serious injury, and was not in the least likely to die, and in fact he recovered perfectly.

Judging by the title of the second discussion it would appear to be a subject of interest to the army and navy man only, but in reality it concerned the civil practitioner as much as, if not more than, the military man. That the question of the reduction of venereal disease among soldiers and sailors was a vital one was evidenced by the public notice which it had attracted. It had been brought up in parliament, and it had been made the subject for the next Parkes' memorial prize.

The number of men suffering from venereal diseases in the army was enormous. For example, the ratio per 1,000 of soldiers in India "constantly sick" of venereal disease during the year 1897 was 39.41; in the West Indies during the same year it was 35.56; and at home it was nearly 12 per 1,000.

If this was the whole story, then the discussion might properly be left to military surgeons, but unfortunately the mischief did not end here. The management of syphilis in the army, owing to the impossibility in most cases of carrying out a sufficiently long continued plan of treatment, was eminently unsatisfactory, and every year numbers of discharged soldiers and sailors suffering from syphilis were let loose upon the community and convey the disease to women and, through them, to children, so that what with the probability of future outbreaks of syphilis in the men themselves and the infection of women and children there could be no question that the health of a considerable portion of the community was seriously impaired. The prevention and treatment of syphilis in the navy and army was a subject therefore in which all physicians were deeply concerned.

Mr. Butlin then reviewed briefly the titles of the papers announced in the programme which, he said, bore the promise of rich fruit.

**Diagnosis and Treatment of Gunshot Wounds of the Abdomen.**—Colonel Stevenson, R.A.M.C., professor of military surgery at Netley, opened the appointed discussion on this subject. The importance of the subject from a military surgeon's point of view could hardly be overrated, while to the civil surgeon the subject was of great, and from the apparently increasing frequency in civil practice of these cases, and increasing interest. In both cases the diagnosis rested on the same appreciation of symptoms, but the treatment in civil and military practice was often different. In civil life the lines on which operation should be performed were clearly laid down, civil practice having been freed from the dread of interference with a serous membrane. In military surgery the apparent slower recognition of the capability of modern surgery in cases of gunshot wounds of the abdomen was in reality due to the conditions under which these cases had to be treated. The wounded men were often left a long time on the field of battle before being picked up, this being an adverse factor in treatment. Then any procedures adopted must be carried out in the field hospitals, in which the personnel was kept as low as possible. The work in these hospitals was done at high pressure, and the military surgeon had to bear in mind the greatest good to the greatest number, and thus often aid might be given to many patients in the same time that one laparotomy—often a tedious process—would take up. Penetrating wounds of the abdomen, when healed by the expectant treatment (*i.e.*, rest and opium), were probably the most fatal class of cases due to injury. In the Crimea 92.9 per cent. of cases resulted fatally; in the American war ninety per cent. He estimated that perhaps in reality only one per cent. of the wounded recovered, and the difference between apparent and real mortality was due to actual penetration not having taken place in eight or nine per cent. of the cases. He believed that when a bullet traversed the abdomen we might rely on the presence of one or both of two conditions: extravasation of intestinal contents or hemorrhage—in either of which a fatal issue was certain. The present indication as to treatment was quite distinct. The abdomen should be opened, the intestines sutured or any bleeding point secured, and the peritoneum closed. Since about 1885 this subject had been actively taken in hand. Mere exploratory laparotomy had been shown to present a very small mortality, and holding as he did that when a projectile had entered the abdomen it was futile to expect safety of the viscera, laparotomy was always called for. He referred to Marion Sims' paper and suggestions on this subject. In battle about fifteen per cent. of the wounds were found to be abdominal, of which the majority of patients died on the field. The chief cause of death was hemorrhage. Hemorrhage in the abdominal cavity was often very profuse and seldom stopped spontaneously. To control it laparotomy must be done. Wounds of the intestine were seldom simple; a bullet generally punched out a piece of gut equal in area to the bullet's cross-section, and as a rule the intestine was wounded in more than one place. In such cases he thought it a waste of time and words to insist on the chance of no ill result. Laparotomy, and that immediately, was called for. If solid organs, the spleen or kidney, were damaged, they would probably require to be removed, or the patient would die of hemorrhage. When the diagnosis was once made he thought the laparotomy should be immediate, every half-hour lessening the patient's chance of recovery. The only excuse for delay in military surgery was overcrowding in the field hospitals, or absence of requisite supply of antiseptics. Whereas the mortality of those operated on within twelve hours of receipt of the injury was fifty-three per cent., it rose during the next twelve hours to seventy-seven per cent.

Mere contusions of the abdomen, as by a fragment of a shell, or in civil practice by buffer accidents, might be accompanied by rupture of blood-vessels, solid organs, or intestinal tube, and laparotomy would be called for. In these cases symptoms alone must be relied on. The three primary symptoms to be looked for were shock, vomiting, and pain. But their severity must not be taken as a measure of the extent of the injury. The diagnosis must be based on their presence, persistence, progress, and duration. The differential diagnosis between contusion with rupture and contusion without rupture must depend on the symptoms increasing or diminishing in severity. If due to contusion only they diminished; if internal injury was present they increased in severity. The order of frequency in which the viscera were wounded was liver, spleen, kidneys, stomach, small intestine, and lastly large intestine. The value of tympanites as a symptom of perforation of the intestine, and escape of gas into the peritoneal cavity, he considered of no certain value.
